Figure 2 shows H_2 accumulation curves as a function of time for different temperatures, where the saturation vapour pressure of water was used in each case. To inhibit the recombination of H_2 and O_2 products, a few grammes of 0.025 mm Cu foil was placed in the reaction cell to getter the O_2 present. Without this extra copper to oxidize, and thus remove active O_2 from the system, less than half the H_2 would be detected. Oxidation of Cu by water with a release of H_2 was ruled out by blank experiments. Thus the recombination of hydrogen and oxygen is a significant process in these conditions. This is not surprising in view of the presence of platinum and a light activated semiconductor, either of which might act as a catalyst. Because of this back reaction, O_2 was not detected. Blank experiments showed no hydrogen production without platinum on the crystal, nor with platinum on an alumina substrate, and very poor production when platinum was deposited on the dark side of the crystal.

The curves in Fig. 2 show an induction period which depends on exposure to water vapour. If the crystal is exposed to water vapour in the dark for 1–2 h, hydrogen production will proceed immediately on illumination. However, when the crystal is illuminated *in vacuo* for the same period and then exposed to water vapour, the induction period is observed. Thus there is

Fig. 1 Apparatus: A, stainless steel cell; B, UV light from Hg lamp; C, sapphire window; D, SrTiO_3 crystal with Pt on the side facing the light. Water vapour circulates through cell, pump, and sampling valve.

Fig. 2 H_2 product accumulation for four different temperatures at H_2O saturation vapour pressures. Δ , 160 °C, 6 atm; $\circ$, 140 °C, 3.5 atm; $\square$, 120 °C, 2 atm; ∇ , 100 °C, 1 atm.

evidence for a slow surface reaction, such as hydroxylation or displacement, which seems to be a necessary precursor for the efficient catalytic photolysis of water observed after the induction period. During efficient hydrogen production, a rate of as much as 500 monolayers per hour has been observed. Within ~ 10 h, however, the hydrogen production rate diminishes. Besides equilibration of the production and recombination rates there is also a surface poisoning effect which contributes to this decline. If a crystal used in the experiment is not regenerated by replacement of the platinum coating, it will yield much less hydrogen in a subsequent experiment. A similar deactivation was noted by Wrighton *et al.*¹ in the SrTiO_3 -Pt electrochemical cell.

It was possible to carry out the photolysis of water at less than saturation vapour pressure. At constant pressure, the reaction rate declines with increasing temperature, as expected, because the recombination over platinum is more facile at higher temperatures. At constant temperature, the rate of hydrogen production increases with increasing pressure.

Recently we reported the photocatalysed dissociation of water vapour on platinum coated and metal-free SrTiO_3 crystal surfaces which were covered with a film of NaOH (refs 2, 3). The need for NaOH was traced to the importance of hydroxylation of the oxide surface. In the conditions of the present experiment the surface is expected to be hydroxylated⁴, and this effect is apparently equivalent functionally to the effect of NaOH.

In conclusion, we have observed evidence for the following steps during photolysis of water on platinized SrTiO_3 : (1) generation of electron-hole pairs by light of greater than bandgap energy; (2) dissociative chemisorption of water vapour on the hydroxylated semiconductor surface; (3) diffusion of a surface hydrogen species to platinum islands and desorption of hydrogen from the islands; and (4) recombination of hydrogen and oxygen which limits the amount of hydrogen that can be generated in a batch reactor.

Fluid inclusion Rb–Sr isochrons for dating mineral deposits

T. J. Shepherd & D. P. F. Darbyshire

Isotope Geology Unit, Geochemistry and Petrology Division,
Institute of Geological Sciences, 64 Gray's Inn Road,
London WC1X 8NG, UK

The precise dating of mineral deposits has important implications for understanding the lifetime of ore-forming systems and their temporal relationship to various geological events. Not all deposits provide material suitable for conventional radiometric dating, or data which are amenable to unequivocal interpretation. Nor is it easy to verify that such samples have remained isotopically 'closed' since their formation. Fluid inclusions provide an alternative 'closed system' approach. By analysing the isotopic composition of Rb and Sr in inclusions within quartz from the Carrock Fell tungsten vein deposits, Cumbria, we demonstrate here the feasibility of obtaining Rb–Sr fluid inclusion isochrons. The age for the mineralization 392 ± 5 Myr is in good agreement with the mean K–Ar age 387 ± 6 Myr for the vein micas, and confirms the significance of fluid inclusions as precise Rb–Sr geochronometers.

Fluid inclusions are small, usually microscopic, volumes of fluid trapped within crystals during their growth from the fluid. To be used as geochronometers their origin must be known and also that nothing has been added or lost from the inclusion after sealing. The inclusions have usually been trapped at more than one stage in the growth and subsequent fracturing and healing of the crystal. For the purposes of dating, however, as long as the various inclusions were formed in a relatively short time interval, the crystal can be treated as a single temporal event. For a more complex chronology, samples representing individual episodes of mineral deposition can be selected.

In most geological conditions inclusions do not leak¹ although exceptions are excessive overheating² and the development of an intracrystalline deformation fabric³ within the host mineral. The former leads to thermal rupture with a complete emptying of the inclusion, whereas the latter may vary from a simple 'drawing-out' of the inclusion with minor leakage, to total rupture and destruction. Host minerals with little or no cleavage and good mechanical strength are thus preferred. Quartz, a ubiquitous mineral of hydrothermal ore deposits is suitable, particularly as its high chemical purity permits analysis of the inclusion contents independently of ion impurities in the host crystal.

Inclusions provide a means of applying basic geochronological concepts to situations where conventional mineral and rock studies have failed. Excluding fission track dating, the use of inclusions as geochronometers has the same restrictions as all radiometric methods of dating.

(1) The mineral or rock samples must have behaved as 'closed' systems with respect to the parent–daughter isotopes according to the equation

$$D = D_0 + P(e^{\lambda t} - 1)$$

where D is the total number of daughter atoms present in the system; D_0 the number of daughter atoms initially present; P , the number of parent atoms remaining in the system; λ , the decay constant for the parent radionuclide; and t , the time elapsed ('age' of the system). (Inclusions in transparent minerals can be checked before analysis to ascertain whether thermal

rupture or intracrystalline deformation has caused them to leak.)

(2) The mineral or rock samples were formed in a time interval that was short compared with their age. (Modern hydrothermal–hot spring systems driven by local igneous heat sources have lifetimes of a few thousand to approximately one million years. Presumably palaeohydrothermal systems associated with igneous rocks had similar lifetimes. Hydrothermal ores precipitated on the sea floor are thought to have had formation times of a few thousand years because they contain little detritus, even though the rocks above and below are normal detrital sediments⁴.)

(3) A value for the initial number of daughter atoms (D_0) can be assumed or calculated.

Inclusions in quartz can be thought of as droplets of fluid preserved, totally isolated from their external environment, and perfect for Rb–Sr dating. The only disadvantage is their small size, normally $<20 \mu\text{m}$ in diameter. For a fluid containing 1,000 p.p.m. Sr a single inclusion may provide less than 10^{-12} g Sr for analysis.

To test the feasibility of using fluid inclusions as Rb–Sr geochronometers for ore deposits we have taken samples from the tungsten deposits at Carrock Fell, Cumbria. These deposits are characterized by a series of steeply dipping north–south wolframite-bearing quartz veins developed at the contact of the Caledonian Skiddaw Granite with the Lower Palaeozoic Skiddaw Slate Series. Mineral paragenesis studies^{5,6} suggest a main period of hydrothermal activity characterized by continuous quartz deposition, with wolframite and apatite confined almost exclusively to the earliest generations of quartz. Much of the quartz is therefore economically 'barren'. Late-stage hydrothermal activity is represented by a network of cross-cutting east–west carbonate veins and stringers, some of which cement and infill vuggy parts of the quartz veins. Compared with the tin–tungsten deposits of south-west England, the mineralization constitutes a simpler hydrothermal event, which with data from a previous geochronological study⁵ was ideal for investigation. The samples were selected from an extensive suite of vein quartz material collected from underground workings at the Carrock Fell Mine and were representative of both the early and late phases of quartz deposition. The quartz contains abundant two-phase fluid inclusions consisting of a liquid phase and complementary vapour phase, the latter occupying $<25\%$ of the total inclusion volume. They average $5\text{--}30 \mu\text{m}$ in diameter, are ovoid or multifaceted in form, and occur in both isolated non-planar groups and discontinuous intersecting planar arrays. Genetically the inclusions are primary, but because it is difficult to relate them to obvious growth features they are best described as pseudosecondary^{7,8} (they correspond to fluids trapped along microfractures during crystal growth). Collectively the inclusions can be treated as the product of a single mineralizing

Fig. 1 Fluid inclusion Rb–Sr diagram. Age, 393 ± 5 Myr; intercept, 0.70997 ± 0.0004 ; MSWD, 1.42.

Table 1 Rb–Sr data for inclusion fluids, Carrock fell tungsten deposit, Cumbria

Sample no.	Rb (p.p.m.)	Sr (p.p.m.)	$^{87}\text{Rb}/^{86}\text{Sr}$	$^{87}\text{Sr}/^{86}\text{Sr}$
CF-79-10	446	287	4.511	0.73465
	512	281	5.289	0.74043
	475	298	4.625	0.73577
	388	278	4.041	0.73239

	1,112	301	10.77	0.77102

event. Unlike the pseudosecondaries, secondary inclusions are less well developed and clearly associated with the late-stage carbonate fluids. They can be recognized by their distinctive chemistry and behaviour during low temperature microthermometric studies. Samples suspected of containing either secondaries or inclusions which had leaked were rejected.

The sample preparation and mass spectrometric analysis will be described elsewhere. Conventional isotope dilution techniques⁹, modified to accommodate low level, small samples, were used (the results, given in Table 1, are plotted in Fig. 1). Analytical errors ($\pm 1\%$ $^{87}\text{Rb}/^{86}\text{Sr}$; $\pm 0.03\%$ $^{87}\text{Sr}/^{86}\text{Sr}$) agree with those normally assigned to precision Rb–Sr mineral/whole rock isochrons. The Rb–Sr age was calculated¹⁰, using an ^{87}Rb decay constant of $1.42 \times 10^{-11} \text{ yr}^{-1}$, with errors quoted at the 2σ level. A MSWD of 1.42 indicates that the data satisfy the criteria for an isochron.

The fluid inclusion Rb–Sr age $392 \pm 5 \text{ Myr}$ is in good agreement with the mean K–Ar age for the hydrothermal vein muscovites $387 \pm 6 \text{ Myr}$ determined by Rundle⁵. Furthermore the age of the main Lake District batholith, of which the Skiddaw Granite is part, has been established as $\approx 395 \text{ Myr}$ (Shap Granite, Rb–Sr age $394 \pm 3 \text{ Myr}$ (ref. 11), K–Ar age $397 \pm 7 \text{ Myr}$; Skiddaw Granite, K–Ar ages $392 \pm 4 \text{ Myr}$ (ref. 5) and $399 \pm 6 \text{ Myr}$ (ref. 12)). As the veins cannot be older than the granite and there is no reason to doubt the K–Ar vein muscovite age, the agreement verifies the fluid inclusion Rb–Sr age. A noticeable feature of the isochron (Fig. 1) is the large range in $^{87}\text{Rb}/^{86}\text{Sr}$ which minimizes the influence of the initial $^{87}\text{Sr}/^{86}\text{Sr}$ on the calculated age. This is attributed to a variable input of Rb throughout the period of quartz deposition, either from a purely magmatic source or released into the ore fluids as a result of concomitant wallrock alteration (that is, greisenization). High Rb values are consistent with the preferential partition of Rb into magmatic–hydrothermal solutions¹³. Because the inclusions are largely pseudosecondary in origin, no two samples will contain identical proportions of the same generation of inclusion. Hence there will be a natural variation in the observed $^{87}\text{Rb}/^{86}\text{Sr}$ ratios.

The fluid inclusion approach seems superior to techniques that rely on the complete resetting of pre-existing systems (that is, the annealing of fission tracks in wallrock minerals adjacent to mineral veins¹⁴). Furthermore being relatively stable, inclusions are less sensitive to subsequent thermal events which often overprint the true age of mineralization. This is especially so for K–Ar studies on wallrock clays which show a poor retentivity for radiogenic argon. Of comparable significance is the ease with which K–Ar systematics can be reset by later meteoric–hydrothermal activity¹⁵. Because later hydrothermal solutions will often take advantage of earlier mineralizing channels, caution must be exercised when interpreting the K–Ar ages for feldspars and clays¹⁶. There is no *a priori* means of assessing whether a system has remained closed. It is also suspected that meteoric–hydrothermal activity may equally disturb Rb–Sr systematics. As yet the common Pb method for dating lead mineralization is only applicable to a small number of deposits of

the 'conformable' type. Recent refinements of terrestrial lead isotopic growth curves has done much to improve this technique and 'model' ages agree well with ages obtained by other methods. However, for most ore deposits, lead isotopic compositions indicate multistage histories which are not readily amenable to interpretation.

We thank R. Pankhurst for the development of programmes for the automatic running of the mass spectrometer, also D. Norman whose early isotopic work on fluid inclusions in Norwegian granites stimulated our research. The project was financed in part by the Commission of the European Communities Raw Materials Research Programme: Contract No. 038-79-1 MPP UK. Publication is by permission of the Director, Institute of Geological Sciences (NERC).

Biogeochemical significance of a novel sedimentary C_{27} stanol

S. C. Brassell & G. Eglinton

Organic Geochemistry Unit, University of Bristol,
School of Chemistry, Bristol BS8 1TS, UK

Recent studies^{1–3} of the lipids of marine organisms have revealed numerous novel sterols, many with modified side chains. As yet few of these compounds or their diagenetic products have been recognized in geological materials. However, recent investigations of various marine sediments^{4–8} have detected, for example, gorgosterol⁴ (IIo) and several 4-methylstanols^{7,8} (such as III/). Our gas chromatography (GC) and computerized gas chromatography–mass spectrometry (C-GC-MS) investigations of the extractable lipids in Neogene deep-sea sediments from the Japan Trench have revealed highly complex sterol distributions within which 69 different sterols have been characterized⁹. Several of these sterols^{9,10} (such as II_m, II_n and III_o), have been reported as constituents of marine organisms^{11–13}, but not of marine sediments; others are of unknown structure. Here we report the identification of one of these novel sterols, 27-nor-24-methyl-5 α -cholestan-3 β -ol (Ih) which supports the biological demethylation pathways proposed by Kobayashi and Mitsunashi¹². Its diagenetic products would also include 27-nor-24-methylcholestanes which may be unrecognized components of the sterane mass fragmentograms widely used by petroleum geochemists for oil and source rock fingerprinting. Such components might also prove valuable marine markers in the interpretation of palaeoenvironments.

Fig. 1 Structural formulae of steroidal nuclei (N, I–VI) and side chains (R, a–q). The sterols I, II and III, bearing a wide range of side chains, are produced by organisms^{1–3,11–13,22–24} and occur in sediments^{4–10}. In contrast, the 5β -stanols (IV and V) and the Δ^2 -sterene (VI) are apparently derived from microbial and/or geochemical processes, and are often prominent components of immature sediments^{8,9,21,27,28}; however, the known variety of their side chains is less extensive than that of stenols and 5α -stanols.

During Legs 56 and 57 of the Deep Sea Drilling Project (DSDP), the Glomar Challenger drilled at seven sites in a transect of the Japan Trench^{14,15}. Our studies concentrated on the extractable lipids of 10 samples of Upper Pleistocene (~0.5 Myr) to Upper Miocene (~6 Myr) age, from four of these sites, with the aim of understanding the origin and diagenetic fate of the lipids^{9,10,16}. The analytical procedure used to obtain free sterol fractions from these sediments followed that previously described¹⁷, with subsequent modifications^{16,18}. Briefly, the extractable lipids obtained by sediment ultrasonication with solvent were divided into neutral and acidic components following saponification, and thin layer chromatography was used to separate the total neutrals further into fractions principally composed of hydrocarbon, ketone and alcohol constituents. Each fraction was analysed by capillary GC (SE-52 or OV-101 columns, deactivated by the barium carbonate technique of Grob *et al.*¹⁹) and C-GC-MS after derivatization (for example, of alcohols to their trimethylsilyl (TMS) ethers) when appropriate.

27-Nor-24-methyl- 5α -cholestan- 3β -ol (Ih) was identified from its GC retention time and mass spectral characteristics and by GC and C-GC-MS co-injection with a standard prepared by hydrogenation (PtO_2/H_2 in EtOAc) of ocellasterol (27-nor-24-methylcholest-5,22E-dien- 3β -ol, IIg). Its mass spectrum (as a TMS ether) is indistinguishable from that of 5α -cholestan- 3β -ol (Ij, Fig. 2), but the retention times of these two compounds differ (Fig. 3). Previous analyses of sedimentary sterols may not have

recognized 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih) because of the prominence of 5α -cholestan- 3β -ol (Ij) in such distributions and the necessity of fast scanning GC-MS (for example, 1 s scans) to distinguish the two compounds satisfactorily.

In the Japan Trench sediments, which are principally diatomaceous oozes and clays, the concentration of 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih), with the exception of one sample that contained only trace amounts (<0.1 ng per g dry sediment), varied from 0.6 to 11.7 ng per g dry sediment; values that correspond to 0.2 to 1.2 μg per g organic carbon. In four samples 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih) was more abundant than 5α -cholestan- 3β -ol (Ij), attesting its importance as a sedimentary sterol.

Although the origin of 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih) is uncertain, it seems to be biological rather than geochemical. No apparent correlation exists between its abundance and that of the other 27-nor-24-methylcholesteroids with $\Delta^{5,22}$ (occellasterol (IIg)) and Δ^{22} (Ig) unsaturation, data that argue against its formation by geochemical reduction²¹. In addition, 27-nor-24-methylcholest-5-en- 3β -ol (IIh) would be an expected product of such a nonspecific reduction process, but it was not detected in any of the sediments. Furthermore, the presence of only two 5β -stanols, 5β -cholestan- 3β -ol (IVj) and 5β -cholestan- 3α -ol (Vj), rather than a range commensurate with that of the Δ^5 -stenols and 5α -stanols indicates that reduction of Δ^5 -stenols is not a significant process in Japan Trench sediments and suggests that the 5α -stanols in the C_{21} – C_{31} range⁹, are derived directly from biological inputs.

The identification of 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih) means that both 27-nor-24-methylcholesteroids and 24-norcholesteroids are now known to occur as $\Delta^{5,22}$ -stenols and Δ^{22} - and 5α -stanols, supporting the demethylation pathways proposed by Kobayashi and Mitsuhashi¹². The organisms that act as the biological source of 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih) are unclear. Its C_{26} homologue, 24-nor- 5α -cholestan- 3β -ol (If) has only been isolated from a sponge²²; both this compound and other sponge constituents, such as C_{21} – C_{24} 5α -stanols (Ia–d) (refs 23, 24), have been recognized in the Japan Trench sediments^{9,16}, where sponge spicules are also found^{25,26}. Hence, 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih) may be of poriferan origin.

Considering the geological fate of 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih), at an early stage of diagenesis stanols can undergo dehydration, generating Δ^2 -sterenes^{27–29}. The Δ^2 C_{27} sterene in the Japan Trench sediments which eluted just after cholest-2-ene (VIj) and possessed an identical mass spectrum is, therefore, probably 27-nor-24-methylcholest-2-ene (VIh); if so, then the diagenetic reactions of 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih) parallel those of 5α -cholestan- 3β -ol (Ij) (refs 8, 9, 27–29). Hence, 27-nor-24-methyl- 5α -cholestan- 3β -ol (Ih) could be a precursor for other sedimentary steroidal hydrocarbons with 27-nor-24-methyl side chains, particularly diasterenes³⁰, aromatic steroids³¹ and steranes, which might prove valuable indicators of marine sources of sedimentary organic matter. The possible existence of such 27-nor-24-methylcholestanes has a bearing on petroleum geochemical studies in view of the widespread use of steranes as biological markers³³. In particular, the process of diagenesis and maturation effect sterane isomerization, generating a wide range of stereoisomers^{32,33}; hence, mature sediments and oils would be expected to contain a comparable variety of 27-nor-24-methylcholestane isomers. Significant amounts of such compounds would markedly complicate the mass fragmentograms used for sterane evaluation^{32,33}, and also affect the quantitation of individual stereoisomers.

Novel compounds are likely to continue to be found in marine sediments because of the role of sediments as 'sinks' for organic matter. For example, the novel C_{27} $\Delta^{5,22}$ -stenol, Δ^{22} -stanol and 5α -stanol in the Japan Trench sediments may possess 26,27-bisnor-23,24-dimethyl side chains (IIp, Ip and Iq in Fig. 3), as recently suggested³ for similar components in Walvis Bay diatomaceous ooze⁴.

Fig. 2 EI mass spectra (40 eV, background subtracted) of: (a) 5α-cholestan-3β-ol (Ij); (b) 27-nor-24-methyl-5α-cholestan-3β-ol (Ih), as TMS ethers. The data were obtained from C-GC-MS analysis of the alcohol fraction separated from a Lower Pliocene diatomaceous claystone (DSDP Section 57-440B-39-3, 504m sub-bottom depth). The C-5 stereochemistry of (b) is assigned on the basis of its chromatographic characteristics and mass spectral fragmentation which are indicative of a 5α-stanol rather than a 5β-stanol⁸.

Fig. 3 Partial reconstructed ion chromatogram (RIC) from C-GC-MS analysis of extractable 4-desmethylsterols (as TMS ethers) in a Lower Pleistocene diatomaceous clay. □, Δ^5 -stenols; ■, 5α -stanols. The C_{26} and C_{27} sterol region is illustrated with designated peaks referring to the structures of Fig. 1. The 5β -stanols (IVj and Vj) found in this sample were present in the 4-methylsterol fraction (not shown). C-GC-MS conditions; 20 m OV-1 WCOT capillary column programmed, after splitless injection, from 50 to 100 °C at 6 °C min⁻¹, then 100 to 260 °C at 4 °C min⁻¹ and held isothermally at 260 °C. The mass spectrometer (Finnigan 4000 with INCOS 2300 data system) was scanned cyclically at 35 eV with complete mass spectra (m/z 50–560) being recorded every second. Data acquisition was initiated at 165 °C. A more extensive RIC of this sterol fraction is published elsewhere¹⁰.

We thank NERC (GR3/2951 and GR3/3758) for C-GC-MS facilities and a studentship (S.C.B.) and Dr M. Kobayashi for an authentic sample of ocellasterol. We acknowledge our colleagues associated with the DSDP project at Bristol and Mrs A. P. Gowar for assistance with C-GC-MS analyses.

Rate of dune reddening in a humid tropical climate

K. Pye

Department of Earth Sciences, University of Cambridge,
Downing Street, Cambridge CB2 3EQ, UK

The formation of red beds has long interested geologists and pedologists^{1–3}. It has been suggested that the nature and degree of reddening in dune sands can be a useful indicator of the relative age and environmental history of the sands; several authors have concluded that dune sands undergo progressive reddening with time^{4–7}, and James and Stanley⁸ considered that coastal dunes might actually be mapped on the basis of colour. However, quantitative data regarding the rate of reddening in different environmental conditions are generally lacking. I present here radiocarbon evidence from north-east Australia which suggests that red weathering profiles have developed in stabilized dunes of Holocene age in humid tropical conditions within the past 7,500 yr.

Deeply weathered siliceous sand dunes occur on several parts of the North Queensland coast, Australia, but are most extensive around Cape Bedford, Cape Flattery, and Shelburne Bay (Fig. 1). The dunefields consist of several generations of elongate parabolic dunes, the youngest of which are still partly active. The older stabilized dunes are deeply podsolized, with typical profiles on dune crests consisting of 1–4 m of leached white sand overlying 6 m or more of red and orange ferruginous sand (Fig. 2). The colour of the sands below the A horizons is variable, with banding and mottling characteristic of the lower profile, but the reddest B horizons attain 2.5YR4/8 (moist) on the Munsell soil colour chart. The red colour is due to iron oxides and hydroxides which cannot be positively identified by X-ray diffraction but which probably consist largely of poorly crystallized forms of haematite containing a certain amount of water. Bulk samples of red sand contain up to 0.668% of dithionite citrate extractable Fe, together with up to 0.75% extractable Al. The pigment is present both as coatings on framework grains and as interstitial matrix.

Air photograph interpretation and field drilling have shown that at least three distinct episodes of dune formation are represented at Cape Flattery. Dunes belonging to both the first and second episodes show evidence of reddening, but the colouration is most marked in dunes of the second generation. The forms of the oldest dunes are highly degraded and the sands contain black horizons of organic matter-cemented sandrock which are particularly well developed in low-lying depressions.

Fig. 1 Map showing location of Cape Flattery and other coastal dunefields in North-east Australia.

Some dunes show that part of the red pigment is being removed by progressive podsolization. A radiocarbon date obtained from a large root in growth position and embedded in humate⁹ exposed in coastal cliffs 3 km north-west of Cape Flattery indicated a 'background' age of 48,000 ^{14}C yr (Q-2085). Similar deposits occur in Southern Queensland¹⁰ and New South Wales where they have been shown to be last interglacial in age¹¹.

The forms of the second generation of dunes, which drilling has shown to overlie partly the first generation, are relatively sharp and the sands contain only very thin, non-indurated humate horizons. A typical weathering profile found in dunes of this generation is shown in Fig. 2. Two radiocarbon dates have been obtained from samples of charcoal collected at depths of 2 and 4 m respectively within this profile. The charcoal was pretreated with an alkali-pyrophosphate mixture followed by acidification to remove humic acid contaminants. The upper charcoal sample gave a date of $7,480 \pm 75$ ^{14}C yr BP (Q-2081), and the lower sample indicated an age of $8,200 \pm 85$ ^{14}C yr BP (Q-2082). As the charcoal fragments must have been incorporated within the sands while the dune was active, the dates suggest that stabilization and weathering has taken place within the past 7,500 ^{14}C yr. The possibility that the charcoal is reworked from older deposits cannot be entirely ruled out, and in this event the dates would indicate a maximum age for the reddened dune.

The youngest dune sand unit at Cape Flattery includes all the active and recently active dunes which have partly buried and reworked the older sands. These dunes mostly consist of undifferentiated white quartz sand, but those which have been stabilized longest show immature podsol development with brown or brownish-orange B horizons. Buried organic Al

horizons are exposed in the walls of some dunes. Two radiocarbon dates on *in situ* wood stumps from one such buried soil including a 1 m-thick brownish B horizon both indicated 'modern' ages (SRR-1534 and SRR-1535).

Previous work on red sediments has led to the conclusion that reddening is generally slow, and in arid regions may take 10^5 – 10^6 yr (refs 12, 13). However, the evidence reported here suggests that in humid tropical conditions bright red colours may be attained within 10^3 – 10^4 yr. Furthermore, over a longer time period much of the initial red colour may be lost as humic and fulvic acids accumulate within the profile. A similar conclusion was reached, though without radiocarbon evidence, by Andriess¹⁴ in relation to reddened beach ridges and alluvial deposits in Sarawak.

Rapid reddening of stabilized dunes at Cape Flattery is favoured by several factors. First, abundant detrital ilmenite and magnetite grains within the sands provide a large potential source of iron which can be released by weathering^{15–19}. Second, rapid release of iron and formation of ferric oxides is favoured by oxidizing interstitial conditions which reflect the good drainage of the dune sands and the seasonally humid tropical climate. At Cooktown, located just south of Cape Flattery, mean daily temperature is above 25 °C throughout the year, reaching 31.3 °C in December, while about 75% of the mean annual rainfall occurs between January and April. Third, weathering of ilmenite, magnetite and other minerals may be enhanced by organic acids released by the heath and woodland vegetation characteristic of the dune areas^{20,21}. Soil pH values at Cape Flattery generally lie in the range 3.5–5.5.

Rate of reddening in dune sands and other recent sediments is dependent on several variables including sand mineralogy, temperature, moisture availability, drainage conditions, degree of sediment stability and significance of airborne dust input²². Climatic conditions undoubtedly permit reddening in both the arid and humid tropics, but, other things being equal, the time required to attain a given degree of redness is likely to be longer in the arid tropics due to lower moisture availability, a slower rate of mineral weathering and relative unimportance of biochemical processes. In humid tropical areas periods of seasonal

Fig. 2 Diagrammatic representation of a weathering profile exposed in a section through a stabilized dune near Cape Flattery. Radiocarbon dates Q-2081 and Q-2082 refer to charcoal samples (x) 248 and 249 respectively. Charcoal sample 250 was analysed for chemical purposes.

drought and water table lowering can also be expected to favour the formation of haematite²³. However, owing to the diverse nature of the controls on reddening, time cannot be regarded as an independent variable in the reddening process, and colour alone cannot be used as an adequate guide to age or morpho-stratigraphic correlation between different areas.

This research was supported by NERC and the RS. Radiocarbon age determinations were made by Dr Roy Switsur and by the NERC Radiocarbon Dating Laboratory, East Kilbride.

Internal plumbing of Mount Etna

J. E. Guest

University of London Observatory, Mill Hill Park,
London NW7 2QS, UK

A. M. Duncan

Geology Section, Luton College of Higher Education,
Luton LU1 3JU, UK

A number of conflicting models have been proposed for the internal plumbing system of Etna; some of the conflict arises from attempts to fit the same model to the whole of Etna's history. We argue that at present magma reaches the surface without significant high-level storage during its ascent, and that eruptions are tectonically controlled. These conditions have probably prevailed for the past 200 yr. However, evidence from lavas erupted in prehistoric times suggests that substantial low-pressure differentiation accompanied by different styles of eruption took place, implying a different plumbing system which includes high-level storage of magma.

Etna is a central-vent volcano some 3 km high, with numerous parasitic cones. The position of the central conduit has shifted with time, each change in location generally being preceded by caldera collapse¹. Almost continuous activity occurs at or near the summit where there is a steady effusion of lava, normally at the rate of less than 1 m³ s⁻¹, accompanied by strombolian activity. A curious aspect of summit activity is that two craters less than a few hundred metres apart may simultaneously show quite different activity; for example, in 1966 to 1971 the north-

east crater was erupting lava on the surface, while only 200 m away, activity in the chasm was ~1,000 m below this level. Persistent summit activity usually stops when flank eruptions occur—these are characterized by much higher rates of effusion, typically at tens of cubic metres per second. Feeding fissures tend to parallel the complex regional tectonic pattern.

Based on petrological evidence, Rittmann² envisaged that magma is supplied under Etna by abyssal fissures and that there is no magma chamber. Guest³ suggested the existence of a plexus of dykes and sills within or just below the volcanic pile, analogous to that proposed for Kilauea⁴. From horizontal ground deformation studies between 1971 and 1974, Wadge^{5,6} postulated two magma reservoirs: one at the base of the volcanic pile, and the other an open cylindrical reservoir in the upper part of the central conduit. The central conduit reservoir, known as the chasm, was envisaged by Wadge as feeding flank eruptions by first opening fissures radial to the chasm as a result of hydraulic fracturing and subsequent drainage of the reservoir under gravity through these fissures. Tanguy and Kieffer⁷ suggested high-level magma storage in active dyke-like intrusions, eruption from which was triggered by tectonic activity.

Studies of vertical ground deformation have been made between 1975 and 1980⁸. During this time persistent activity occurred from the north-east crater and the north-east rift between 1975 and 1978, and flank eruptions occurred on the southern flank between May 1978 and August 1979. Following the established deformation pattern at Kilauea, while relatively little deformation might have been expected from some of the persistent activity at the summit, substantial effusion low on the volcano flanks should have been preceded by inflation caused by high-level magma storage, followed by deflation as the chamber emptied. However, during 1975–80, including the major August 1979 flank eruption during which an estimated minimum of 8 × 10⁶ m³ of magma was erupted (C. Kilburn, personal communication), no gross pattern of inflation or deflation was observed either by precise levelling traverse across the summit, or from some 35 dry-tilt stations. Based on five years of tilt measurement on Etna, there is no evidence that large amounts of magma are stored within the volcano before eruption, and if it is stored in an intermediary reservoir, this lies well below the base of the volcano. Thus internal conditions at Etna seem to differ from those of Kilauea.

Although no gross accumulation of magma within the Etna volcano can be identified, small vertical movements do occur. A 1.5-cm inflation area of ~1 km radius was observed two years before the May 1978 eruption in the region of the main vent, suggesting that a narrow wedge of magma was emplaced below the eruption site before effusion started⁹.

Although the vertical deformation results do not support a high-level magma chamber in a conventional sense, they are not inconsistent with Wadge's⁶ proposal of an open chamber in the chasm at the top of the central conduit. However, Wadge's model requires that the chasm drains during the course of flank activity and that the amount of lava drained corresponds to the volume of lava erupted. These conditions have not been fulfilled by recent eruptions when, for example in April 1971, the chasm floor was lower than the active flank vents³. Thus, although the Wadge model is not discounted as a potential mechanism, it cannot be considered as a general model to explain Etna's plumbing system during 1970–80 (see also ref. 9).

Based on seismic evidence, Sharp *et al.*¹⁰ suggested a magma storage region at a depth of ~20 km below Etna. This has the form of a prolate ellipsoid with a width ~20–30 km and the long axis paralleling the north-east fissure trend through the mountain. From the same experiment they identified the Moho at 27 km, magma generation occurring below this level.

During historical times the lavas have been basic hawaiites with little variation in chemical composition^{11–13}. Historic lavas are strongly porphyritic with 30–40% phenocrysts of plagioclase, augite and olivine, plagioclase being the dominant phenocryst phase; the magma therefore undergoes extensive

crystallization before eruption. Limited variation in chemistry between lavas indicates that there is little differentiation. The predominance of plagioclase suggests that most of the crystallization takes place at moderate to low pressures. Experimental work¹⁴ on an alkali basalt shows that crystallization of plagioclase is suppressed to near solidus temperatures at pressures approaching 9 kbar, equivalent to ~22 km depth. These observations imply that considerable crystallization is taking place at relatively high levels, but the magma is erupted before significant differentiation occurs. This is consistent with the ground deformation interpretation that there is no substantial high-level magma storage. Magma stored in the open central conduit may, however, undergo vapour-phase fractionation¹⁵⁻¹⁸.

Although the composition of historical lavas has remained almost constant, there are petrographic distinctions, for example the 1974 flank eruption lavas^{7,19,20}, where plagioclase was not a primary phenocryst phase. In this case either the crystallization of plagioclase was suppressed by high P_{H_2O} conditions, or magma migrated from depth rapidly containing only early formed phenocrysts of augite and olivine.

The evidence given above supports the view expressed by Rittmann² that on Etna magmas ascend directly to the surface

from depth without storage in a high-level magma chamber. These observations agree to some extent with the model proposed by Tanguy and Kieffer⁷ of a system of active intrusions. It is likely that magma enters the volcanic pile permissively and a high level of magma in an open central conduit gives steady persistent activity. Dyke-like intrusions leading to flank eruption radiate at various depths from the central conduit and may be emplaced in tectonically dilated fissures. Eruptions are controlled both in space and time by the interaction of magma fluid pressure and the regional stress pattern (see ref. 21): a decrease in the minimum horizontal principal stress will increase the gape of dilational fissures, allowing an increased rate of magma uprise. The presence or absence of a cinder cone over the vent, for flank eruptions, will depend on the depth of connection between the feeder dyke and the conduit (Fig. 1a). Eccentric cones result from ascent of magma independent of the central conduit, for example, the Moio cone 18 km north of the summit²². The role of the 20-km deep magma reservoir is uncertain, but the observation that repose time between the end of a flank eruption and the onset of persistent activity is proportional to the volume of erupted material in the flank eruption⁶ may suggest that the repose period is controlled by the time taken for the reservoir to be replenished.

Fig. 1 a, Interpretation of the present internal structure of Mount Etna. Magma rises up the central conduit from a deep magma storage area. Low effusion rate persistent activity from this conduit occurs near the volcano summit. A column of magma is probably always present in the central conduit and associated conduit of the north-east crater, at levels of less than a kilometre below the volcano's summit. The opening of fissures by tectonic activity allows magma to leave the central conduit at different depths to produce flank eruptions with high effusion rates compared to persistent activity. Occasionally eccentric eruptions may occur as a result of magma rising directly from the deep magma storage area using a conduit not related to the central conduit. The dimensions of the magma storage area and the seismic velocity profile are from ref. 10. b, Condition of the volcano during pre-Valle del Bove times, showing high level plexus of dykes in which magma is stored. Although the different styles of activity are shown on the same diagram, the normal activity was probably strombolian with occasional extrusions of volcanic domes and paroxysmal events.

Geophysical information is only available for the past few years on Etna. Nevertheless, interpretations of internal plumbing based on these data are probably relevant for the past 200 yr, during which time the petrology of the lavas, styles of eruption and output of the volcano have been relatively constant. However, before 1669 the output of the volcano was considerably higher²² and the erupted lavas petrographically different from the more recent ones, although of hawaiitic composition. These earlier lavas are characterized by larger phenocrysts of plagioclase, typically 4 mm long, compared with those in later lavas which are ~1 mm long. The presence of fewer phenocrysts may imply a short period of high-level storage. A plexus of active dykes near the base of the volcanic pile may have existed at this time⁶. Thus, even during historic times the internal plumbing of Etna seems to have changed; these alterations may have resulted from variations in the regional stress pattern.

At times in the prehistoric past of Etna (5,000–100,000 yr BP), before formation of the Valle del Bove¹, a very different system of internal plumbing may have operated in the volcano. Among the older volcanics, evolved lavas of mugearitic and benmoreitic composition are relatively common, indicating more extensive differentiation of the ascending magma^{11–13}. Plagioclase is considered to have played a major part in this crystal fractionation¹⁸ suggesting that at one time there was high-level magma storage. Ash fall and ignimbrite deposits occur^{23,24}, indicating violent explosive events in the summit region, possibly associated with caldera collapse and de-gassing of a high-level magma reservoir (Fig. 1b). On the lower flanks of the volcano, relatively degassed magma was erupted, which formed benmoreitic autoclastic domes¹⁸ probably fed from a storage area that had been degassed by loss of volatiles up the central conduit.

We make the following conclusions: (1) there is no simple model of volcano plumbing that can be applied to central basaltic volcanoes, and a long-lived central volcano made up of repeated eruptions may not have the same type of plumbing throughout its history. (2) Petrogenetic models based on a whole suite of lavas spanning a long time period may be misleading as in this case, where different models involving the presence or absence of a high-level magma reservoir are applicable to different phases in the volcano's plumbing history. (3) Because a volcano's plumbing is controlled by factors such as the regional stress pattern, rate of magma supply and rate of stress adjustment in the magma source region, a study of Etna's changing internal conditions may have direct relevance to the regional tectonic evolution.

Anti-predator function of bluegill sunfish nesting colonies

Wallace J. Dominey

Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853, USA

Although the adaptive significance of nesting in colonies has been investigated repeatedly in avian species, until now no detailed studies have been reported on colonial nesting in fishes. Investigators of avian colonial systems have suggested that birds nest in colonies either as a response to predators^{1,2} or to locate more easily ephemeral food resources^{3,4}. The avian literature is unclear, however, as to which selective pressure (predation or food resources) is more crucial, with investigators using similar evidence to reach essentially opposite conclusions⁵. I report here evidence obtained from a long-term study of a colonial fish, the bluegill sunfish (*Lepomis macrochirus*), showing extreme synchrony in breeding and the additional protection afforded offspring by tightly clustered groups of adults, which argues strongly that colonial nesting in this species and other fishes has evolved in response to predation pressure.

Observations on the reproductive system of the bluegill sunfish were made during the summers of 1976, 1978 and 1979 while skin or scuba diving in Lake Cazenovia, New York. In this lake, male bluegills construct nests (bowl-shaped depressions in the substrate) in colonies ranging in size from 15 to 500 nests. Throughout the breeding season males periodically reoccupy, breed in, and abandon these nesting areas. Although suitable nest sites are not limited (in preparation), during the spawning period occupied nests are packed rim to rim, with most nests having five to seven contiguous neighbours (Fig. 1).

As early as 1938, Darling⁶ suggested that colonially nesting birds might breed synchronously to reduce the time their young are available to local predators. However, in avian systems, an alternative hypothesis also predicts breeding synchrony. If nesting colonies serve as 'information centres' that enable unsuccessful or inexperienced foragers to follow more successful individuals to ephemeral food sources, individuals breeding in synchrony would gain an advantage⁷. Because colonially nesting fishes typically neither feed their young nor leave the colony to forage, the competing hypothesis of social foraging does not apply. Consequently, the presence of breeding synchrony in these organisms would provide stronger support for the predation hypothesis than synchronous breeding in avian systems.

If predation is the evolutionary force favouring colonial nesting in bluegills, individuals within a colony should synchronize their reproductive efforts, resulting in greater breeding synchrony within colonies than between colonies. As predicted by this hypothesis, breeding within bluegill colonies in Lake Cazenovia is remarkably synchronous. At a particular colony breeding episodes occur periodically, and consist of the establishment of males on nests, the arrival of gravid females which remain in the water column until spawning is initiated, and a brief 1- or 2-day spawning period. Between these spawning periods gravid females are absent and successful males provide parental care. Although common responsiveness to optimal breeding conditions seems to promote a degree of breeding synchrony among all the colonies in Lake Cazenovia, synchrony within colonies is much greater than between colonies, as predicted, and even neighbouring colonies can cycle out of phase.

The period immediately following the termination of parental care is often critical to an individual's survival. During this period, bluegill fry minimize their availability to predators by abandoning their nests synchronously, with most of the offspring in an entire colony leaving within a period of a few hours. Analogous fledgling synchrony has been reported in some

Fig. 1 An artist's conception of the activity in a bluegill colony during the spawning period. An aggregation of females is shown above a spawning centre (top centre). Multiple spawning partners (centre right) can indicate the presence of a 'female mimic'¹², a small sexually mature male that mimics female behaviour while 'stealing' fertilizations from nesting males. Nesting males are shown mobbing a large predatory turtle (top right), fanning eggs (right middle) and swimming rapidly around the perimeter of their nests in 'rim circling' displays (bottom right).

colonial birds⁸. In fish, as in birds, the impact of predation by locally available predators should be reduced when large numbers of offspring become available over a short period of time (as many as 100,000 in a single bluegill nest). The extreme synchrony observed both in breeding and nest abandonment argues strongly that colonial nesting in bluegills serves an anti-predator function.

In addition to synchronous breeding, active defence can limit the availability of the offspring of colonially nesting animals to predators. In a colony where each parent defends an area around its nest, if defended areas overlap, the offspring might benefit from the cumulative defence of several individuals. The offspring of colonially nesting birds have been found to gain such an advantage, with nests in high-density areas being better protected than those in low-density areas⁵, and this type of advantage has also been suggested for colonially nesting fishes⁹⁻¹¹. In the case of bluegills, evidence of a colony structure that promotes overlap of defended areas would support further the hypothesis that colonial nesting is a response to predation pressure, as would evidence that offspring in high-density areas gain additional protection.

Female bluegills select mates such that males guarding nests are found in more tightly packed groups than one would predict if females were indiscriminately selecting mates. During the spawning period, gravid females are attracted to spawning pairs and deposit their eggs in adjacent nests, creating areas of spawning activity or 'spawning centres'^{12,13}. Bluegill males whose nests are not located in these spawning centres often fail to receive eggs, or receive too few eggs to merit parental care, and abandon their nests following the spawning period. Might the spawning response of female bluegills function to ensure that their offspring are adequately protected from predation by a tightly compacted group of defending males?

Attempted predation was common in the bluegill colonies of Lake Cazenovia, occurring more frequently than has been reported in avian colonial systems. In a typical 10-min observation period, a bluegill male defended its nest several times against potential egg predators. In 950 min of cumulative observation, the most common piscivore egg predators were foraging (not nesting) conspecifics (72%) and members of the closely related species *Lepomis gibbosus*, the pumpkinseed sunfish (21%).

To test whether the offspring in nests in tightly clustered groups receive additional protection against predators, I

removed males from both isolated and surrounded nests, then recorded the number of egg predators present in the nests at 1-min intervals for 10 min. Nesting males were not observed to forage in temporarily vacated nests. Isolated nests (having no more than one neighbouring nest) were more vulnerable to egg predators than were surrounded nests (having five or more neighbouring nests) (Fig. 2). Not only did the presence of defending neighbours make it more difficult for foraging fishes to enter a focal nest, but neighbouring males often actively attacked egg predators foraging in the focal parentless nests, with isolated nests receiving significantly fewer defences by neighbours than surrounded nests (Fig. 2). The additional protection afforded to nests in high-density areas is expected to result both from the 'selfish herd' effect¹⁴, by which individuals passively gain from the presence of neighbours, and from the overlap of defended areas. Both protective effects should extend readily to other types of predators attacking bluegill offspring.

The biological significance of these findings is supported by two observations. (1) Offspring in parentless nests sometimes survive to the freeswimming stage because of the incidental protection of neighbouring males. (2) Foraging schools composed of bluegills and pumpkinseeds sometimes harass isolated nesting males until these males are no longer effective at nest defence; this results in complete loss of brood. I never observed the nests of males in high-density areas to be similarly overrun, apparently because of the incidental protection provided by neighbouring nest-defending males. The inability of isolated males to defend their nests against egg predators, especially those foraging in schools, has probably been a major selective force promoting colonial nesting in centrarchid fishes.

This hypothesis is supported by the observation that those centrarchids which frequently nest solitarily or in loose association (for example, *Micropterus*, *Ambloplites* and *Pomoxis*) are larger, more piscivorous fishes than those that typically nest colonially, such as *Lepomis macrochirus*, *Lepomis megalotis* or *Lepomis punctatus*, even in the same habitat. These larger, more piscivorous forms are probably able to defend their nests better against foraging schools¹⁵. Such superior capability alone, however, is an inadequate defence for isolated nests when sunfish are present in high densities. In these conditions the nesting success of even the largest, most piscivorous forms, such as *Micropterus*, can be severely limited¹⁶. Finally, as foraging schools of bluegills are such predominant and effective predators on the eggs of conspecifics, wherever bluegills occur and

Fig. 2 Two observers simultaneously removed nest-guarding males from *a*, isolated nests (having no more than one neighbouring nest) and *b*, surrounded nests (having five or more neighbouring nests), then recorded the number of egg predators present in each nest at 1-min intervals for 10 min, and the total number of defences by neighbouring males. Surrounded nests had significantly fewer cumulative egg predators ($P < 0.001$, Mann-Whitney) and received significantly more defences by neighbouring males ($P < 0.001$, Mann-Whitney).

nest, an effective egg predator will also occur. Thus bluegills might be considered their own worst enemies, and may themselves have generated much of the selective pressure promoting their extreme form of colonial nesting.

Induction of subacute murine measles encephalitis by monoclonal antibody to virus haemagglutinin

Kottil W. Rammohan, Henry F. McFarland & Dale E. McFarlin

Neuroimmunology Branch, National Institute of Neurological and Communicative Disorders and Stroke, National Institutes of Health, Bethesda, Maryland 20205, USA

Although the events which predispose a host to measles virus persistence remain largely unknown, measles antibody has been shown to contribute to the production of a persistent infection by this virus both *in vivo* and *in vitro*. Thus, the addition of measles antibody to cells infected with measles virus promotes virus persistence^{1,2}. Latent measles infection occurs in newborn hamsters with maternally acquired antibody after inoculation with measles virus in the immediate neonatal period³. A subacute encephalitis with measles virus persistence has been induced in weanling BALB/c mice that received antibody after virus inoculation⁴ and in measles-immune primates infected with a virus derived from a patient with subacute sclerosing panencephalitis⁵. Measles virus consists of six polypeptides, and treatment of measles-infected cells with antibody has been shown⁶ to alter the pattern of their synthesis. As the antigenic specificity of the antibody responsible for these observations is not known, we decided to investigate the effects of monoclonal antibodies directed against the individual measles polypeptides. We report here that a monoclonal antibody directed against the virus haemagglutinin, unlike an antibody to the virus nucleocapsid protein, is able to induce a subacute encephalitis *in vivo*.

After the intracerebral (IC) inoculation of weanling BALB/c mice with $10^{2.7}$ ICD₅₀ units of hamster neurotropic (HNT) measles, about 70-80% of the mice die from an acute encephalopathy. This encephalopathy produces mortality within the first 3 weeks and is characterized by a complete absence of brain inflammation, although neuronal viral antigen is readily demonstrable⁷. If hyperimmune measles antiserum (HI serum) is administered 3 days after virus inoculation, all the mice survive the acute period, but ~30% develop a delayed disease and die. Its onset is variable and has been observed up to 8 weeks post-inoculation. It is characterized by weight loss, seizures, and multiple neurological abnormalities that are fatal in a few weeks. Unlike the acute encephalopathy where brain inflammation is absent, histopathology of this subacute disease is characterized by mild inflammatory response of the meninges and parenchyma. Thus, it is referred to as an encephalitis. Immunofluorescence of the frozen sections from moribund animals shows abundant viral antigen in neurones of the hippocampus, frontal cortex, brainstem and cerebellum⁴. Mice which do not develop the subacute disease (~70%) have been observed for up to 6 months and remain well.

The HI serum used to induce the subacute encephalitis was prepared by hyperimmunization of BALB/c mice with Edmonston measles virus⁴. The serum has reactivity to all polypeptides of the measles virion. However, the polypeptide specificities of the antibody molecules in this panreactive serum that are responsible for this *in vivo* effect are unknown. To investigate this question, ascitic fluid containing monoclonal antibodies with single specificities against the virus haemagglutinin (C1 AF)⁸ and virus nucleocapsid protein⁹ was tested in this system for the ability to modify disease. Administration of the C1 AF abolished the acute encephalopathy and led to the development of a subacute disease which lasted up to 70 days. Two representative experiments, out of eight, are shown in Table 1. Large doses of C1 AF inhibited disease completely and with decreasing amounts of antibody the incidence of the

Four-week-old female BALB/c mice were inoculated with $10^{2.7}$ ICLD₅₀ units of HNT measles virus in 0.03 ml in the right cerebral hemisphere under light ether anaesthesia, using a tuberculin syringe and 30 G needle. All animals received 0.2 ml of the appropriate dilution of antiserum through the tail vein on day 3 post-inoculation. Control animals received nothing. Transfer of normal mouse serum in previous experiments were without effect on the onset or course of clinical disease. Characteristics of antisera used were: HI serum, serum pooled from 50 female BALB/c mice after hyperimmunization with purified Edmonston measles virus. Initial immunization was with complete Freund's adjuvant followed by multiple boosts (13 boosts over 18 months) in saline or incomplete Freund's adjuvant. The serum titres were: 1:1,024 by haemagglutinin inhibition test, 1:2,048 by complement fixation test, $>10^{-4}$ by virus neutralization test and 10^{-6} dilution by radioimmunoassay. The serum reacts with all polypeptides of the Edmonston measles virus in a radioimmunoprecipitation assay³. PS X63 AF, ascitic fluid prepared from pristane-primed BALB/c mice inoculated with the parent myeloma cells used to produce the 79 XI-C hybridomas⁶. 79 XI C1 AF, ascitic fluid prepared from pristane-primed BALB/c mice inoculated with 79 XI-C hybridoma. The ascitic fluid had reactivity only with the haemagglutinin of Edmonston measles virus. The ascitic fluid titres were: 1:4,000 dilution in virus neutralization, 1:4,000 in haemagglutinin inhibition and 10^{-7} dilution in a solid-phase radioimmunoassay. The antihaemagglutinin antibody is identified as IgG1 subclass⁶. All mortalities were recorded from the day of virus inoculation. Mortalities within the first 21 days were arbitrarily considered 'acute' and subsequent mortalities were included in the 'delayed' group. Mean survival time was calculated as the mean duration from the day of inoculation to the day of death (range indicated in parentheses). Daily mortalities; superscript number indicates the total mortality for the day (d) indicated.

subacute clinical disease increased. At the greatest dilution (1:500) used, protection from the acute disease was not absolute (expt 2, Table 1). In animals receiving the lower doses of antibody the onset of the subacute illness was earlier and the total mortality greater. These observations suggested an inverse correlation between the dose of antibody transferred and total mortality, and, furthermore, that the onset of clinical illness may be related to the fall in serum antibody. This was supported by studies correlating the antibody levels with the onset of clinical illness. Following transfer, the antibody levels declined, and were barely detectable when clinical illness began. Transfer of large amounts of monoclonal antibody to the virus nucleocapsid protein did not affect the acute mortalities in three experiments. Similarly, no effect was observed with normal mouse serum or ascitic fluid obtained from the parent myeloma (P3 X63)⁸.

The virological and pathological features of the delayed encephalitis were studied. One hundred weanling BALB/c mice were inoculated with $10^{2.7}$ ICLD₅₀ units of HNT measles virus and given 0.2 ml of a 1:100 dilution of the C1 AF through the tail vein on day 3. Every 5 days viral expression in the brains of five infected animals was studied by direct immunofluorescence. A fluorescein-conjugated IgG purified from the serum of a patient with subacute sclerosing panencephalitis capable of reacting with all measles polypeptides was used¹⁰. On day 8 after virus inoculation, the brains of all five animals had viral antigen, which was detectable in occasional neurones. On days 13 and 18 viral antigen could no longer be detected in any of the 10 brains studied. At day 23 viral fluorescence was readily observed bilaterally in all five animals. The onset of clinical illness followed shortly afterwards in the remaining mice. The animals with clinical encephalitis had viral antigen detectable in the neurones of the hippocampus, frontal cortex, brain stem and cerebellum. Brains from moribund animals were also studied by light microscopy. These showed meningeal and parenchymal perivascular cuffs of mononuclear cells. However, the degree of inflammation was considerably less than in chronic encephalitis described in the SJL mouse¹⁰ or disease induced by the panreactive serum in BALB/c mice⁴.

Clearly, unlike the antibody to nucleocapsid protein, antibody with reactivity only to the virus haemagglutinin can modify the clinical course of acute murine measles encephalitis. Although

the precise mechanisms whereby C1 AF delays the acute encephalopathy are unknown, the effect may be through antigenic modulation *in vivo*. The haemagglutinin is expressed on infected cell surfaces and is available for modulation by antibody. The observed disappearance of all viral antigens from the central nervous system at days 13 and 18 suggests that the reaction between the haemagglutinin peptide and the anti-haemagglutinin antibody alters the synthesis of all viral polypeptides *in vivo*. Similar effects have been observed in experiments *in vitro*⁶.

The HI serum contains antibody against the fusion protein which is also expressed on infected cell surfaces. Although antibodies to fusion protein may also be important in antigenic modulation of infected cells, *in vitro* studies suggest that this antigen is available for interaction with its antibody only in the Fab monomeric state at least on the surface of some infected cells¹¹. However, monospecific antibody to the fusion protein of another paramyxovirus, SV5, inhibited the spread of infection by limiting cell fusion and virus entry after virus adsorption¹². The effect of antibody to the fusion protein on the modulating ability of the HI serum remains to be determined. The results from this study establish that antibody to one surface component, the haemagglutinin, is responsible for some of the *in vivo* effects of the HI serum. The antibody reactivity not only leads to delayed clinical disease but alters the synthesis of viral polypeptides in infected cells.

We thank Drs Barry Bloom and M. Birrer for providing the hybridoma cells with antinucleocapsid reactivity, and Mrs Shirley Sutphin and Gail Raoofi for secretarial assistance.

Acute rabies death mediated by antibody

Bellur S. Prabhakar* & Neal Nathanson

Department of Microbiology, University of Pennsylvania Medical School, Philadelphia, Pennsylvania 19104, USA

Among inadequately immunized laboratory animals dying of rabies, a small but consistent proportion succumb after an incubation period shorter than that of any of the unvaccinated controls^{1-3,7} and this phenomenon has been termed 'early death'. It has also been shown that, after immunosuppression either with cyclophosphamide or by thymectomy and irradiation⁴, rabies-infected animals survive longer with decreased incidence of paralysis. It appears that 'early death' also occurs in humans who have been treated (unsuccessfully) with vaccine, with or without accompanying serum therapy⁵⁻⁷, after exposure to rabies. Collectively, these studies suggest that there is an immunopathological component in rabies virus infection. We have therefore investigated a model of lethal rabies infection in immunosuppressed mice and have concluded that B lymphocytes or antibody specific for rabies play a part in the causation of early death. Accordingly the immune response to rabies has a dual role⁸, sometimes favouring survival but sometimes enhancing the disease.

In this study, we used the high-egg-passage Flury (HEP) strain of rabies virus, which causes a limited inapparent infection of the central nervous system (CNS) in adult mice⁹ that can be converted into a fatal infection by immunosuppression¹⁰. This fatal infection can in time be aborted by adoptive transfer of syngeneic immune spleen cells¹¹. Adult BALB/c mice were lethally irradiated by total body irradiation (TBI) from a ¹³⁷Ce source (800–850 rad). TBI and normal mice were infected intracerebrally (IC) on the day of irradiation with 5,000 suckling mouse ICLD₅₀ of HEP virus. As shown in Table 1, untreated TBI mice died due to radiation; but could be protected by normal bone marrow cells devoid of mature T lymphocytes. Normal mice infected with HEP virus survived, but HEP-infected TBI mice died despite immunological reconstitution with bone marrow cells, clearly separating rabies death from that due to radiation.

HEP-infected TBI mice reconstituted with normal spleen cells or cells from donors immunized 30 days earlier (memory cells), died after a mean survival time (MST) of 9 days, but spleen cells from donors immunized 7 days earlier (primary immune cells) conferred complete protection with animals showing no apparent symptoms of the disease.

However, adoptive transfer of spleen cells obtained from donors 3 days after secondary immunization (secondary immune cells) resulted in early death of 28% of the recipients, while the rest survived. The animals that died within 2–3 days after cell transfer did not show any signs of paralysis, typical of rabies, but rather acute symptoms such as convulsions and tonic spasms. Onset of these symptoms was noted only a few hours before death. Histopathological examination of parasagittal sections of the brain from nine of these animals that were either moribund or just dead showed no inflammation, neuronal destruction or other alteration. By contrast, in brains obtained immediately after death from a group of eight mice dying of rabies 13–15 days after infection, foci of necrotic hippocampal cells with minimal inflammation were consistently seen.

To characterize further the immunological requirements for early death, secondary immune spleen cells from syngeneic donors were separated into B- and T-cell enriched populations by passage through a nylon wool column¹² or by treatment with anti- θ antibody and complement. TBI mice infected with HEP

Table 1 Effect of TBI and adoptive cell transfer on HEP virus infections

10–12-week old BALB/c mice were irradiated (800–850 rad, TBI) and on the same day were inoculated with 5,000 suckling mouse ICLD₅₀ of HEP virus. Four days later, these mice were injected intravenously (i.v.) with 10⁷ bone marrow cells or 10⁸ spleen cells from syngeneic donors. MST, mean survival time (days) for mice that died, counting from the 4th day of infection when cells were transferred.

* Indicates mortality within 72 h of cell transfer.

† Indicates primary or secondary immune cells and the time of collection, in days, after last donor immunization.

Table 2 Induction of antibody-mediated death in TBI and HEP virus-infected mice

Immunotherapy	Early death* (%)	Total mortality (%)
B cells	6/27 (22)	100
T cells	0/24 (0)	100
Anti-rabies antibody	6/24 (25)	100
Normal serum	0/12 (0)	100

10–12-week old BALB/c mice were irradiated (800–850 rad) and, on the same day, inoculated with 5,000 suckling mouse ICLD₅₀ of HEP virus. T and B cells were obtained from donors immunized with rabies virus 33 and 3 d before collection of spleen cells; 60 × 10⁶ fractionated viable cells were given i.v. on day 4. Mouse hyperimmune anti-rabies antibody and normal serum were given intraperitoneally in volumes of 0.5 ml each on day 4.

* Death within 72 h of cell or serum transfers.

were given enriched B cells, T cells, mouse anti-rabies antibody or normal mouse serum. The data summarized in Table 2 show that either immune B lymphocytes or rabies-specific antibody, similar to secondary immune cells, can induce early death, whereas T lymphocytes failed to do so. The failure of B or T lymphocytes or antibody to protect is probably due to incomplete immunological reconstitution of these animals^{11,13–15}.

These results clearly demonstrate that early death from rabies virus is mediated by antibody rather than by immune T cells. However, the mechanisms by which the antibody precipitates the disease are not obvious. Although it is well established that anti-rabies antibody plus complement can lyse rabies-infected cells in culture¹⁶, involvement of such a mechanism in early CNS lesions needs further study. This model may lead to further understanding of the contribution of host immunological responses to rabies pathogenesis, and may also be relevant to the pathogenesis of obscure virus-initiated human diseases such as the acutely fatal encephalopathy of Reye's syndrome.

We thank Dr T. J. Wiktor for allowing this work to be done in his laboratory at the Wistar Institute, and Drs G. A. Cole and J. R. Klein for their critical comments. This work was supported in part by USPHS grants NS 16010, AI 09706 and CA 09410.

Monoclonal antibody identifies a new Ia-like (p29,34) polymorphic system linked to the HLA-D/DR region

Lee M. Nadler*, Philip Stashenko†, Russell Hardy*, Kevin J. Tomaselli*, Edmond J. Yunis‡, Stuart F. Schlossman* & John M. Pesando*

The Divisions of Tumor Immunology* and Immunogenetics‡, Sidney Farber Cancer Institute–Harvard Medical School, Boston, Massachusetts 02115, USA

Department of Immunology†, Forsyth Dental Center–Harvard School of Dental Medicine, Boston, Massachusetts 02115, USA

The Ia antigens of the mouse are the basis for the genetic control of the immune response. The HLA-D/DR locus is considered to be the human counterpart of the Ia subregion of the murine major histocompatibility complex^{1–4}. The HLA-D/DR antigens are polymorphic, and eight well defined alleles have been identified using alloantisera⁵. More recently, 'supertypic' antigens (MB and MT) have been defined which identify clusters of HLA-D/DR specificities^{6–9}. Little is known about the molecular basis for the cellular and serological polymorphism of the HLA-D/DR antigens, as alloantisera are usually of very low titre and heteroantisera frequently lack monospecificity. We present here the preparation and characterization of a monoclonal antibody which defines a new polymorphic system of the HLA-D/DR region. This and similar antisera should now begin to provide the reagents with which to correlate molecular structure with the functional repertoire of the human Ia-like antigens.

Six-week old BALB/c mice were immunized intraperitoneally with 5×10^6 ascites tumour cells from a patient with Burkitt's lymphoma. Four weeks later, a mouse was boosted intravenously with 5×10^6 tumour cells and somatic cell hybridization was carried out 4 days later by the modified¹⁰ method of Kohler and Milstein¹¹. Splenocytes (1×10^8) were fused in 30% polyethylene glycol with P3/NS1/1-Ag4-1 myeloma cells (2×10^7) and aliquoted into six microtitre plates (Falcon). Aminopterin was added 24 h after fusion, and macroscopic hybridoma colonies became evident between 10 and 28 days in culture.

Preliminary screening identified several hybridoma antibodies with reactivity limited to: (1) the immunizing Burkitt's lymphoma tumour cell, (2) B-cell lines, but not T-cell lines, and (3) 20–25% of Ficoll–Hypaque fraction of peripheral blood mononuclear cells from normal individuals. All cell-surface characterization was done by standard indirect immunofluorescence assay with subsequent analysis of each population by the fluorescence-activated cell sorter (FACS-I, Becton-Dickinson)¹².

Antisera were then evaluated to determine whether their cellular reactivity was similar to that previously described for anti-Ia-like antisera. The peripheral blood of several individuals

was separated, as previously described¹³, into T, B, monocyte and null cell subpopulations. In addition, purified T cells were stimulated with phytohaemagglutinin (PHA) or concanavalin A (Con A). One antibody, designated I-LR1, reacted with >90% of B cells and monocytes, ~25% of null cells and 25% of Con A- or PHA-activated T cells, but was unreactive with freshly isolated or unstimulated cultured T cells. An identical pattern of reactivity with these fractionated cells was found with the previously reported¹⁴ I-1 monoclonal antibody which defines a non-polymorphic Ia-like antigen. In addition, antibodies I-1 and I-LR1 both identify bimolecular glycoprotein complexes composed of subunits of molecular weights 29,000 and 34,000 (see below and Fig. 1) which have been previously shown using heteroantisera to define human Ia-like antigens^{15,16}. Hybridoma I-LR1 was then cloned by limiting dilution and injected into pristane (Aldrich)-primed BALB/c mice to produce immune ascites¹⁷. Monoclonal antibodies I-LR1 and I-1 were then tested on the B cell-enriched mononuclear cells from 50 healthy

Table 1 Reactivity of I-LR1 with homozygous typing cells

Total		47	46	18

Cryopreserved HTC's were provided by the National Institute of Allergy and Infectious Disease HTC Typing Panel and by the Histocompatibility Laboratory of the Johns Hopkins Medical School. The NIAID HTC panel represented homozygous cells from several typing laboratories, including: (1) the Sidney Farber Cancer Institute, (2) Memorial Sloan-Kettering Cancer Center, (3) Stanford University, (4) Columbia University, and (5) Leiden. These cells were typed for HLA-A, -B, -C, -DR and -D, and are presented by D typing. They include: Dw1 (BVR, OOS, RM-8W104, CAH and J. Beil); Dw2 (FVV, VN2, KJL, TAL, TI, PA, NOL, LA and VML-8W113); Dw3 (AVL, NR3-8W122, NC-3, TPA-8W123, SFN RW, HRA, 2853-8W119 and KF-8); Dw4 (SFN BN, RJM, MWM, GW-8W132, ER-81128 and 5-0107); Dw5 (NAB-8W142 and 6W7006-8W137); Dw6 (HHK, JGr and Daudi); Dw7 (P. Burk, SFN MA, JB12 and MMF); Dw10 (EM10-8W210, FS-8W212 and 2046-8W213); and Dw11 (DMT, MSA, CA, JVM, J. King and D. Beil). (8W represents the Eighth Histocompatibility Workshop designation of the HTC's.) All analyses were carried out on cryopreserved cells with B cell-enriched fractions isolated by Sephadex G-200 anti-F(ab')₂ chromatography. Cells ($1-2 \times 10^6$) were treated with 0.1 ml of a 1:5,000 dilution of an anti-Ia monoclonal antibody or a 1:5,000 dilution of an unreactive control antibody of a similar immunoglobulin isotype, incubated at 4°C for 30 min, and washed twice. The cells were then reacted with 0.1 ml of a 1:40 dilution of a fluoresceinated goat anti-mouse IgG at 4°C for 30 min, washed twice, and analysed on the FACS-I or Cytofluorograf FC200/4800A. Intensity of fluorescence for I-1 or I-LR1 was determined for 40,000 cells in each population by standard indirect immunofluorescence and compared with the fluorescence of an unreactive isotype identical monoclonal antibody. A displacement of the histogram of the test monoclonal antibody compared with the histogram of an unreactive isotype monoclonal antibody was scored positive. In addition, for each test sample, a quantitative assessment of the number of positive cells was made (number of cells reactive with test monoclonal antibody minus number of cells reactive with the unreactive isotype-identical monoclonal antibody divided by 40,000 total cells tested).

* In addition to B cell-enriched fractions isolated from HTC mononuclear cells, 14 HTC's were transformed by Epstein-Barr virus into lymphoblastoid B-cell lines and the identical patterns of reactivity were found for I-1 and I-LR1 (two lines of each of the following D/DR types: 1,2,3,4,5,7,11).

Fig. 1 Serial immune precipitation using monoclonal antibodies I-1 and I-LR1. **A:** *a*, I-1; *b*, I-1; *c*, I-1; *d*, protein A-Sepharose alone; *e*, I-LR1. **B:** *a*, I-LR1; *b*, I-LR1; *c*, I-LR1; *d*, protein A-Sepharose alone; *e*, I-1. The B-lymphoblastoid cell line, Laz 388, was surface-labelled with ^{125}I by the lactoperoxidase method²³. NP40-solubilized membrane extracts were applied to a lentil lectin column and bound glycoproteins eluted with 3% α -methyl-D-mannoside. In conditions of antibody excess, an aliquot of lentil lectin-retained labelled membrane material was incubated three times with I-1 bound to protein A-Sepharose for 14 h at 4 °C. After each extraction, pellets were washed three times in a detergent containing buffer and counted along with a control sample to follow the efficiency of the extraction process. The supernatant was then incubated for 14 h with protein A-Sepharose without added antibody and processed in a similar way to control for any free antibody-antigen complexes which might be present. The supernatant was then incubated overnight with I-LR1 bound to protein A-Sepharose. Similar serial extractions were performed with the I-LR1 antibody. Antigens were resolved by electrophoresis on a gradient polyacrylamide slab gel and visualized by fluorographic processing and autoradiography as described previously²³. Molecular weights are shown.

unrelated HLA heterozygous individuals. Antibody I-LR1 was reactive with the B cells of only 28 individuals, whereas antibody I-1 reacted with all 50, suggesting that the I-LR1 antigen was polymorphic.

To investigate the specificity of I-LR1 further, a panel of homozygous typing cells (HTCs) was examined. As shown in Table 1, I-1 reacted with the B cell-enriched fraction of 46 of 47 HTCs tested, and I-LR1 reacted with only 18 of 47. Moreover, the pattern of reactivity of I-LR1 did not identify a monospecific HLA-D/DR determinant, nor did it identify a previously defined cluster of HLA-D/DR determinants (supertypic). In addition, five separate pairs of HLA-D/DR-identical individuals (pairs including HLA-D/DR 2,3; 4,7; 4,6; and 1,4) displayed reciprocal patterns of reactivity with I-LR1 (for example, D/DR 2,3 reactive, I-LR1 reactive and D/DR 2,3 reactive, I-LR1 nonreactive). This pattern of reactivity on HTCs suggests that I-LR1 defines a new Ia-like specificity.

Additional support for the notion that the I-LR1 antigen was encoded by the major histocompatibility complex was demonstrated by family inheritance studies. As shown in Table 2

(family Kan), I-LR1 reactivity segregates with the maternal 'c' haplotype. This observation strongly suggests that the I-LR1 locus segregates with alleles linked to the HLA complex. Linkage to the HLA-D/DR locus was then demonstrated in families with HLA-D/DR recombinant individuals. As shown in Table 2 (family Sch), the I-LR1 reactivity segregates with the maternal 'c' haplotype. Children 3 and 4 are HLA identical, except at the HLA-D/DR region (see Table 2 legend). B cells from child 3 were reactive with I-LR1, whereas the B cells from child 4 were nonreactive, suggesting that the I-LR1 locus is closely linked to the HLA-D/DR locus. Three additional families (data not shown) provided informative linkage data for I-LR1. For the total of five families (26 of 26 individuals), a determination of the linkage to HLA-D/DR was determined by the lod score method¹⁸, and a very tight linkage to the HLA-D/DR was found ($\theta_{\text{max}} = 0.0$, lod score 6.321). These family studies demonstrate that I-LR1 is linked to the HLA-D/DR locus.

The present study demonstrates that the I-LR1 antibody identifies a polymorphic antigen which shares a pattern of

Table 2 Inheritance of I-LR1 within families

cellular reactivity, molecular weight and HLA linkage with those previously described for human Ia-like antigens. However, the pattern of reactivity on HTC and HLA-D/DR-identical heterozygotes suggests that this antibody defines a new Ia-like antigenic specificity distinct from the known DR, MB and MT specificities. Lampson and Levy¹⁹ have recently demonstrated that two monoclonal antibodies defining non-polymorphic Ia-like antigens identify distinct populations of Ia-like (p29,34) molecules. We now have evidence that the p29,34 molecule identified by I-LR1 is distinct from the p29,34 molecule defined by a monoclonal antibody, I-1 (ref. 14), directed against a non-polymorphic Ia-like antigen (Fig. 1). Extraction of radiolabelled membrane material from the B-lymphoblastoid cell line Laz 388 with I-1 monoclonal antibody removes all the p29,34 glycoproteins recognized by that reagent (Fig. 1A, a-e). When this extracted supernatant was tested with I-LR1, clearly defined gp29,34 complexes were still identified. Identical serial extraction using I-LR1 followed by testing with I-1, produced similar results (Fig. 1B, a-e). As complete extraction of the Ia-like complex recognized by I-1 leaves the Ia-like complex recognized by I-LR1 and vice versa, these antibodies seem to identify different Ia-like molecules which are immunologically as well as genetically distinct.

Using N-terminal amino acid sequencing, several laboratories^{20,21} have demonstrated that the DR and Ia-like antisera so far tested define antigens which share a high degree of sequence homology with murine I-E/C antigens. Recently, Goyert *et al.*²², using peptide mapping and limited N-terminal amino acid sequencing, have found that the heavy subunits of the DRw2 and DRw7 antigens are nearly identical but differ significantly from the respective subunit of the DRw5 antigen. They have, therefore, speculated that DRw5 may represent the human counterpart of the mouse I-A subregion antigen. It is intriguing to speculate that the I-LR1 antigen may identify one allele of a new polymorphic system which may be similarly encoded by the human counterpart of the murine I-A locus. The precise relationship of the I-LR1 antigen to the murine Ia antigens will require further biochemical investigations.

A cyanine dye distinguishes between cycling and non-cycling fibroblasts

R. L. Cohen*, K. A. Muirhead*, J. E. Gill*†, A. S. Waggoner‡ & P. K. Horan*§

* University of Rochester Medical Center, Department of Pathology, PO Box 626, 601 Elmwood Avenue, Rochester, New York 14642, USA

† Department of Chemistry, Amherst College, Amherst, Massachusetts 01002, USA

Cellular proliferative activity has previously been determined by measuring the incorporation of radiolabelled nucleotides or by visual inspection of cellular morphology. Although two flow cytometric methods^{1,2} have recently been developed which can distinguish cycling from non-cycling cells, both have serious disadvantages. One method requires uptake of a substantial amount of BUdR¹, limiting its usefulness for *in vitro* systems. The other method utilizes RNA/DNA content differences² but its successful application has proved cell-type dependent. We have now used the findings that the cell membrane is more highly polarized in resting than in proliferating cells³ and that cyanine dyes carrying a delocalized positive charge enter live cells to an extent that depends on the cell membrane potential⁴, to develop a method of distinguishing between cycling and non-cycling cells. The greater the membrane polarization, the greater is the concentration of dye within the cell. At high concentrations, the dye molecules aggregate and their fluorescence is quenched⁵. Thus, for a given external dye concentration, cells of different membrane potential would accumulate different amounts of fluorescent (non-aggregated) dye. Using fibroblasts in culture conditions chosen to provide various models of cycling and non-cycling cells, we found that fluorescence intensity with the dye 3,3'-diheptyloxycarbocyanine (Di-O-C₇(3))⁶ was consistently greater in the former than the latter.

The human foreskin fibroblasts used in these experiments show virtually no mitotic activity once confluent. In the first

Table 1 Changes in fluorescence intensity of cycling and non-cycling fibroblasts with dye concentration

Dye concentration (M)*	Wound margin†	Confluent region†	Ratio‡	Background§
2.5×10^{-6}	246.0 ± 9.40	183.0 ± 12.7	1.34 ± 0.11	4.80 ± 0.32

Slides were analysed with a Zeiss Axiomat photometer. Fluorescence was excited with epi-illumination from a 100-W mercury arc lamp; the exciter filter was a BP 450-497, the dichroic mirror an FT 510 and the barrier filter an LP 526. Areas of interest on the slide were initially identified with a $\times 10$ or $\times 25$ objective under bright-field phase. Measurements of cytoplasmic fluorescence from selected cells were made with a $\times 50$ 0.95 NA dry objective and an effective photometer aperture of 4- μ m diameter. Fluorescence collected by this aperture was detected by a Hamamatsu R-928 photomultiplier and the output pulses from the tube were detected and counted by a Princeton Applied Research Corporation Model 1105/1120 ratemeter/discriminator. Fluorescence intensity measurements were made immediately after opening the fluorescence excitation shutter. Although some fading or enhancement of fluorescence was observed over a 30-s period, the rate of change was sufficiently low to permit reproducible measurement of fluorescence intensity, as indicated by the standard deviations.

Fig. 1 Fluorescence distribution in fibroblasts stained with the cyanine dye, Di-O-C₇(3). Human foreskin fibroblasts were wounded and stained with 1.0×10^{-7} M Di-O-C₇(3) 4 h after wounding. Fluorescence photomicrographs were taken using a $\times 100$ oil immersion objective and identical exposure times for cells at the wound margin (a) and cells in the confluent region of the same coverslip (b). Maximal definition of the fibrillar structures shown was observed at a stain concentration of 1.0×10^{-7} M. At 5×10^{-7} M more diffuse cytoplasmic staining was observed, although the intensity ratio for wounded and confluent cells was not significantly different at the two concentrations (Table 1). Di-O-C₇(3) (synthesized by A.S.W.) exhibits maximum absorbance at 488 nm (in ethanol) and maximum fluorescence at 504 nm. Stock dye solutions were prepared by adding ~ 1 mg of crystalline dye per ml of ethanol. Stock concentrations were assessed spectrophotometrically, based on an extinction coefficient of 1.49×10^4 M⁻¹ cm⁻¹. Stock solutions were stored for up to 2 months in foil-wrapped tubes at 4 °C. The human skin fibroblasts (donor HS0001, Naval Bioscience Laboratory, Oakland) were used for passages 1–5 and grown at 37 °C on coverslips placed in sealed Leighton tubes containing 10% CO₂. The growth medium consisted of DMEM supplemented with 10% fetal calf serum, penicillin (0.2 units ml⁻¹) and streptomycin (0.2 µg ml⁻¹). Growth medium was changed every 3–4 days. Wounding of monolayers was accomplished by scraping a strip of confluent cells from a coverslip using a modified metal microspatula and sterile procedures. Tubes containing scraped coverslips were returned to the incubator until staining. The cells were stained using the following procedure. Culture tubes were removed from the incubator and the growth medium was removed by aspiration. The slides within the tubes were then rinsed twice before staining. The rinse solution was Dulbecco's phosphate-buffered saline supplemented with 4.5 g l⁻¹ glucose. The staining solution consisted of the above salt solution plus an appropriate concentration of dye. The dye was allowed to equilibrate with the cells for 15 min at room temperature in the dark. Coverslips were then removed from the tubes with forceps, wet mounted using staining solution and sealed with paraffin. Photographs were taken with the 35-mm camera built into the Zeiss Axiomat. Kodak type EH-135 film was exposed for 5 s and developed at ASA 160.

system, we used contact-inhibited confluent cultures grown on glass coverslips as a model for the non-cycling state. A 'wound' scraped in a confluent monolayer releases the cells at the wound margin from contact inhibition³, thus providing both cycling and non-cycling cells on the same coverslip. To determine the maximum fluorescence difference between active and quiescent cells, we examined monolayers at a variety of dye concentrations 4 h after wounding (Fig. 1, Table 1). Table 1 shows that cycling cells were more fluorescent than non-cycling cells over a 50-fold range of dye concentration, with the intensity ratio varying from 1.5 to 5. As the maximum value of the intensity ratio was obtained with 5×10^{-7} M dye, this concentration was chosen for further studies.

The viability of cells in dye was assessed by a double staining experiment using ethidium bromide (1×10^{-6} M) as a measure of the cells' ability to exclude ethidium bromide; dead cells concentrate this dye within their nuclei, while viable cells remain unstained⁷. The cells remained viable and excluded ethidium bromide for at least 2 h in the presence of 5×10^{-7} M cyanine dye, indicating that Di-O-C₇(3) itself is not toxic in these

experimental conditions. In addition, absence of ethidium bromide staining in the cells at the wound margins indicates that cells brightly stained with cyanine dye were not damaged by the wounding process. Thus, the intensity differences shown in Table 1 are not the result of differences in viability of the cell populations.

Intensity differences were also observed in our second model system, using fibroblasts grown to different cell densities. Non-confluent and confluent cells on different coverslips were stained and measured using the previously outlined protocol. As Table 2 demonstrates, the non-confluent (cycling) cells stain more intensely than the confluent (non-cycling) cells.

Table 2 also summarizes the results obtained in the third model system, in which non-confluent cells were incubated for various periods of time in non-permissive medium (0.5% fetal calf serum), in which they become essentially non-cycling cells⁸, and measurements were made as previously described. After 6 days in this media, the cell fluorescence approached that of confluent contact-inhibited cells, although the monolayer was still subconfluent. Visual inspection of cells in low-serum medium did suggest a low level of mitotic activity.

To determine the time required for cells at the edge of a wound in a confluent layer to become significantly brighter than cells in the interior, six confluent monolayers were simultaneously wounded by scraping, returned to media and at various times later stained with 5×10^{-7} M dye for 15 min and then assayed for fluorescence intensity. The results of this experiment (Table 3) may be summarized as follows. (1) Fluorescence changes in the cells at the wound margin were noted as soon as measurements could be made, that is, within 18 min. (2) Maximal fluorescence intensity of the bright cells occurred within 18 min and a constant fluorescence ratio of wounded to confluent cells was then maintained for at least 1 h. (3) The per cent of bright cells at the wound margin increases with time and

Table 2 Effect of growth medium on fluorescence intensity in cycling and non-cycling fibroblasts

Cell density	Growth medium*	Fluorescence intensity†
Confluent monolayer	Permissive	1.00 ± 0.066
Nonconfluent monolayer	Permissive	2.89 ± 0.18
Nonconfluent monolayer	Non-permissive, 52 h	1.71 ± 0.16
Nonconfluent monolayer	Non-permissive, 6 days	1.15 ± 0.084

* Permissive = Dulbecco's modified Eagle's medium (DMEM) + 10% fetal calf serum; non-permissive = DMEM + 0.5% fetal calf serum.

† Means ± s.e. all expressed relative to the fluorescence intensity of the confluent monolayer in permissive medium measured after exposure to 6×10^{-7} M Di-O-C₇(3) as described in Fig. 1 legend.

Table 3 Changes in fluorescence of cycling and non-cycling fibroblasts with time after wounding

Time after wounding (min)	Wound margin	Confluent region	Ratio	Background
3	272 ± 25.3	55.1 ± 4.2	4.94 ± 0.39	1.22 ± 0.06
30	197 ± 15.0	42.5 ± 4.3	4.64 ± 0.59	3.48 ± 0.26
60	204 ± 16.1	46.1 ± 3.6	4.42 ± 0.49	3.35 ± 0.32

The cells were stained with 5×10^{-7} M Di-O-C₇(3) as described in the text at the indicated time after wounding. Staining required a 15-min incubation in dye at room temperature in the dark. Parameters measured were as described in Table 1 legend.

bright cells are eventually noted several cell layers into the confluent monolayer. Mitotic figures and rounded cells are observed at later times.

It is interesting to speculate on the mechanism by which the dye reflects changes in the cycling state of the cells. One possibility is that the dye stains cell cytoplasm relatively non-differentially. Observed intensity differences would then be merely the result of differences in cell size and shape between the two cell populations. Two observations oppose this interpretation. First, microscopic analysis suggests that the size and shape differences between bright cells at the wound margin and those in the confluent monolayer are minimal, especially at early time post-wounding. Second, the intensity ratio of bright to dim cells is concentration dependent (Table 1). If the fluorescent intensity difference merely reflected differences in cell size, the ratio of intensities should remain fairly constant, independent of dye concentration.

A possible mechanism for the observed fluorescence difference is that the dye stains some cytoplasmic structure. Figure 1 shows that the dye does not stain nuclear structures and is localized in discrete filamentous structures within the cytoplasm. Comparison of the morphology of staining in Fig. 1 with that obtained by Johnson *et al.*⁹ using rhodamine 123 suggests that these structures might be mitochondria. Cyanine dyes have been used to stain isolated mitochondria and seem to respond to membrane potential in such systems¹⁰. The timed wound experiments (Table 3) indicate that detection of cycling cells can be accomplished considerably earlier than is possible with methods dependent on DNA synthesis. These results also suggest that some cell parameter—perhaps the cellular or mitochondrial membrane potential—changes very soon after the cells are triggered to begin cycling.

Finally, the intensity differences reported here are large enough to allow good discrimination even in cell populations which have fairly broad fluorescence distributions. Such differences should also make the detection of even relatively small cell populations possible using quantitative techniques for single-cell analysis and sorting¹¹. Di-O-C₇(3) staining therefore promises to provide a fast, easy and sensitive method for distinguishing cycling cells from quiescent cells.

Localization of pacemaking activity in early embryonic heart monitored using voltage-sensitive dye

Kohtaro Kamino, Akihiko Hirota & Shiroh Fujii

Department of Physiology, Tokyo Medical and Dental University, School of Medicine, Bunkyo-ku, Tokyo 113, Japan

Early in cardiogenesis, heart primordia are brought together at the midline and fuse with each other progressively caudally—this results in the formation of the primitive tubular heart which begins beating spontaneously at the middle period of the 9-somite developmental stage in the chick embryo¹. However, in these very early stages of development, the myocardial cells are small and technically difficult to impale with microelectrodes; thus electrophysiological studies on the very early embryonic heart are rare^{2,3}. Recently, potential sensitive dye-related absorption signals have provided a new method for monitoring spontaneous action potential activity in the early embryonic heart^{4–7}. This technique is based on the observation that changes in potential across membrane(s) stained with certain voltage-sensitive dyes are accompanied by changes in their optical properties (absorption, fluorescence, and/or birefringence)^{8–10}. Using absorption signals, we have already demonstrated in embryonic pre-beating chick heart in the 7–8-somite stages, the occurrence of action potential activity^{4,5}, development of pacemaker potential^{6,7} and cardiac rhythm generation⁷. With this method, originally introduced to record neuronal activity in invertebrate ganglia^{11,12}, many cells or portions of the preparation can be monitored simultaneously. Accordingly we have expanded the optical recording apparatus to monitor simultaneously spontaneous action potentials from five portions of an early embryonic heart, and report here experiments carried out on the embryonic hearts of chicks (white Leghorn) at the 7–11-somite developmental stages, corresponding to 25–35 h of incubation. The hearts attached to the embryo were stained with a merocyanine-rhodanine dye (NK2761) as a potentiometric probe. This dye is an analogue of Dye XVII⁹ or Dye XXIII¹⁰.

Figure 1 shows simultaneous recordings of spontaneous optical signals from an 8-somite embryonic heart. The circles overlaid on the view of the embryonic heart in this figure are drawn to scale, indicating the field of optical recording and the relative positions of the light guides. Traces 1, 2 and 4 were obtained from the ventricular region, and traces 3 and 5 from the unfused atrial levels. In the preparation shown in Fig. 1b, both size and shape of each spike in individual traces are approximately uniform, which suggests that the action potentials of active cells in the field of optical recording were well synchronized. However, as shown in traces at the higher sweep speed, there were obvious differences in time course of action potentials from the five different regions; the action potentials in the five different regions were synchronized and there was a small delay between spike 5 and that in the other regions. It is thus likely that the delay corresponds to spreading time of the action potentials. At the 7–8-somite developmental stages, the action potential was usually first detected in the left atrial primordium, but sometimes in the right primordium.

Figure 2 shows experiments demonstrating the spatial distribution of spontaneous action potential activity in the 9–11-somite embryonic hearts. In the preparation shown in Fig. 2a, the action potential first appeared in the left atrial portion (trace 5), and action potentials in other portions (traces 1–4) followed those in the left atrial portion after a delay of 40–150 ms. Furthermore, the light guides were positioned close together in a series on the left portion of a 9-somite embryonic heart. In this experiment, the action potential probably occurs first in the left

atrial level and then spreads progressively in rostral and caudal directions. As shown in Fig. 2b, an action potential also appeared first in the left atrial region in the heart of the 10-somite embryo. Thus, it is reasonable to assume that although both the right and left atria have intrinsic pacemaking abilities, the cardiac rhythm as a whole is governed by the left atrium as the embryo develops from the 7- to the 10-somite stage.

From experiments on the pulsation rate, Patten¹³ suggested that the cardiac pacemaker at the developmental stage of initiation of heartbeat is the atrium. Using microsurgical techniques, DeHaan¹⁴ showed that the earliest pacemaker was on the left

side, and that it shifted to the sinoatrial region only later. Moreover, Van Mierop² was able to record the earliest action potentials in the left atrial region of the 11-somite beating heart, and in the left atrial primordium in the 8-somite embryo, before contractile activity had begun. Indeed, his transmembrane-potential records are remarkably similar to our optical recordings (Fig. 1b). As development proceeded to the 11-somite stage (Fig. 2c), the portion in which the action potential first occurred shifted caudally along the atrium to the sinus primordium.

In embryonic chick hearts past the 13-somite stage, pacemaker potentials were detected electrophysiologically using microelectrodes^{15,16}. We have optically demonstrated differentiation and development of the pacemaker potential during the 8–9-somite stages^{6,7}. At the 8-somite stage, absorption signals resembling the pacemaker potential are widely distributed in the embryonic hearts but by the beginning of the 9-somite stage these signals are localized at the atrial level¹⁷.

In the present experiment, the cardiac-type signals were obtained from the ventricular region and the pacemaker-type ones from the atrial region. The localization of the latter is consistent with the results obtained from experiments on the time course of action potentials, and shows clearly that the pacemaking area is situated in the atrium region at the 9-somite stage.

Fig. 1 A, Chemical structure of a merocyanine-rhodanine dye (NK2761, produced by Nippon-Kankoh-Shikiso Kenkyusho Co.) used as a potentiometric probe in our experiments. The cation associated with the dye is sodium. Voltage clamp experiments in squid giant axons gave good evidence that the absorption signals of merocyanine-rhodanine dyes were linearly related to membrane potential change, and that the optical response followed the voltage change with a time constant of $<20 \mu\text{s}$ (refs 9, 10 and L. B. Cohen, personal communication). B, Spontaneous absorption signals detected simultaneously from five regions in an 8-somite embryonic heart. After the splanchnopleure was carefully peeled off, the isolated embryos were incubated for 15 min in bathing solution containing 0.05 mg ml^{-1} of the dye. After incubation, the dye solution was washed out. The dye was bound to the epi-myocardium cells. The solution used to bathe the embryos was 138 mM NaCl, 5.4 mM KCl, 1.8 mM CaCl₂, 0.5 mM MgCl₂, and 10 mM Tris-HCl buffer (pH 7.2), and was equilibrated with air and allowed to warm to $\sim 37^\circ\text{C}$. This solution was used in most experiments, except those shown in Figs. 2B and C. To measure the absorption of light by the area of interest in the dyed embryonic heart, a $\times 50$ enlarged image of the heart was formed with a $\times 20$, 0.46 n.a. (numerical aperture) objective and a $\times 2.5$ photographic eyepiece, using an Olympus-Vanox microscope (AHB-LB-1, Olympus Optical Co.). Five light guides were used to carry the light from the image of the embryonic heart to each photodiode (Bell and Howell, 509-10). The tips of these guides (4.0 mm in diameter) were positioned over the image of the embryonic heart stained with the dye. The measuring beam was produced by a JC 24V/300W halogen-tungsten-filament lamp (Kondo Sylvania) powered by a current regulated power supply (PAD 35-20L, Kikusui Electronics); the incident light was passed through an interference filter with a centre wavelength of 700 nm and a width at half-height of 11 nm (1F-S, Vacuum Optical Japan). The signals in B were eliminated by illumination with white light, or at 620 nm where the action spectrum of the absorption signal of the merocyanine-rhodanine dyes is zero^{6,7}. Thus, the optical signals shown resemble the spontaneous action potentials in the embryonic heart. The empirical criteria required to distinguish between optical signals from an action potential and those corresponding to movement artefacts have been described previously⁵. In experiments where a relatively low light intensity and brief duration were used, photodynamic damage and dye bleaching were not serious. The fractional absorption change ($\Delta A/A$) is related to the fractional change in transmitted intensity (T); evidence presented below indicates that a decrease in intensity was due to an increase in absorption. $\Delta A/A$ is equal to $-\Delta T/(T_{\text{before}} - T_{\text{after staining}})$, ($\Delta T/T_{\text{after}} = \Delta I/I$). Here, the transmittance calibration bar is indicated. The traces were detected in a single sweep at 37.6°C , and the oscilloscope (Tektronix 5113 Dual Beam Storage Oscilloscope) was set to give a coupling time constant of 1.5 s. The outputs were finally filtered by a simple RC low-pass filter (time constant $\sim 10 \text{ ms}$). Positions 1, 2 and 4 are from the ventricular region, and positions 3 and 5 on the atrial unfused primordia. The field of optical recording encircled in the figure is estimated as 0.005 mm^2 . Traces b were obtained at the higher sweep speed. The embryonic heart is shown in ventral view.

Fig. 2 Simultaneous absorption measurements in five different portions in 9-(a), 10-(b) and 11-(c) somite embryonic chick hearts. Light-guides 1, 2 and 3 were positioned over the image of the ventricular region, and 4 and 5 over the image of the atrial unfused regions in the experiment shown in A. This preparation was obtained just before initiation of the heartbeat⁵. In B and C, traces 1 and 2 were obtained from the ventricular region, 3 and 4 from the atrium, and the position of trace 5 corresponds to sinus primordia. At these stages, the hearts are bent to the right and are pulsating. To reduce movement artifact due to pulsation, we used a hypertonic solution made by increasing NaCl concentration up to 276 mM. In this solution, contraction was reduced. However, such hearts are electrically excitable⁶, as is the case in striate muscle¹⁸. Thus, it is not surprising that no signal was observed by illumination with white light or at 620 nm. It seems likely that differences in the signal size among the different positions are due to tissue thickness and density of the active membrane⁶. Experiments were carried out at 37.3°C (A), 38.3°C (B) and 36.7°C (C).

Fig. 3 Maps summarizing the location of the pacemaking area in the embryonic chick hearts throughout early phases of development, from the 7- to the 11-somite stage. Depth of dotting represents the degree of priority of pacemaking. The arrows indicate the direction of translocation of pacemaking area.

On the basis of these results, we constructed a rough developmental map of regional localization of pacemaking areas during the early phases of cardiogenesis (Fig. 3). The possibility exists that pacemaker cells are situated originally in the cardiac primordia just before and after they fuse in the midline. It seems that as the primitive tubular heart is formed, the pacemaking area which possesses the highest intrinsic rhythmicity, is localized mainly in the left atrial primordium and subsequently in the sinus primordium. With further development of the heart, the

pacemaking cells of the sinus primordium probably become organized into nodes and bundles while maintaining their original relationship with the surrounding musculature.

We thank Drs L. B. Cohen and H. Irisawa for reading the manuscript and for comments and suggestions, and M. Ohara for useful advice. We also thank Nippon Kankoh-Shikiso Kenkyusho Co. for synthesizing the merocyanine-rhodanine dye. The work was supported by grants 457021, 422007 and 387039 from the Ministry of Education, Science and Culture of Japan.

Direct communication between axons and sheath glial cells in crayfish

Camillo Peracchia

Department of Physiology, University of Rochester School of Medicine and Dentistry, Rochester, New York 14642, USA

Evidence for the transfer of molecules as large as proteins from glial or Schwann cells to axons has frequently been reported^{1–8}. This phenomenon is well supported in crayfish^{3,4,8} and squid^{5–7} but there is some doubt about its existence in vertebrates⁹. In invertebrates most of the data support the transfer from glial cells to axons, but little is known about movement of molecules in the opposite direction. However, Grossfeld *et al.*¹⁰ recently reported data on the passage of a fluorescent dye (Lucifer yellow CH, molecular weight (MW) 476) from a crayfish median giant axon to all glial cells of the adaxonal layer. Little is known of the mechanism by which molecules are exchanged between axons and glial cells, but the bidirectionality of the phenomenon in crayfish axons suggests that channels or pores for direct intercellular communication may exist. In most cells, direct communication is provided by gap junctions¹¹ but these structures have never been seen between axons and glial cells of crayfish^{12–14}. Indeed, regions of plasma membrane specialization have been reported¹³, but they are structurally different from gap junctions. I describe here pore structures, observed between 51 axons and glial cells of six crayfish spinal cords, which may represent the means of communication between these cells.

In crayfish, *Procambarus clarkii*, anaesthetized by cooling, the sternal artery was cannulated using polyethylene tubing and perfused with 50–100 USP units of heparin diluted in 10 ml of Van Harreveld's salt solution¹⁵, followed by 40–60 ml of 3–6% glutaraldehyde solution buffered to pH 7.4 with 0.1 M (Na, K) phosphate at room temperature¹⁴. The chain of abdominal ganglia was removed from the animal, washed briefly in 0.2 M phosphate and post-fixed for 2 h in 2% osmium tetroxide buffered with phosphate to pH 7.4 at room temperature. Dehydration was in graded alcohol and embedding in Epon.

Electron microscope examination of thin sections through axons of the abdominal ganglia often show regions where axonal

Fig. 1 Thin section through nerve fibre of a crayfish abdominal ganglion. Axonal and glial cell plasma membranes fuse with each other to form a well defined pore (P). In the region of the pore, tubules of endoplasmic reticulum are aggregated. Inset a is an enlargement of the pore shown in the low power micrograph. Insets b and c show similar pores in other axons, A, axon; G, glial cell; C, connective tissue. $\times 18,000$; insets $\times 77,000$.

and glial cell plasma membranes fuse with each other to create well defined pores between axoplasm and glial cell cytoplasm (Fig. 1). Several such pores are usually grouped in the same region. In these regions there are always aggregates of endoplasmic reticulum tubules and other membrane structures (Fig. 1). The pores generally have 15–20 nm diameters but larger pores are also seen (Fig. 1, insets).

Pores of this size are expected to allow wide communication between axoplasm and glial cell cytoplasm. It seems unlikely that such structures are artefacts of the preparative procedure, as the membranes and other cellular structures of these perfused samples were always extremely well preserved. Furthermore, if the pores were artefacts, one would expect to see them anywhere and not just at regions of endoplasmic reticulum accumulation. Indeed the existence of pores between axons and Schwann cells of invertebrates seems reasonable from a theoretical viewpoint, because only passageways of this size could allow exchange of molecules such as RNA³ and proteins as heavy as 200,000 MW (refs 5, 6).

Potassium channels in the nodal membrane of rat myelinated fibres

Ofer Binah & Yoram Palti

Department of Physiology and Biophysics, Technion—Faculty of Medicine, Haifa, Israel

Following some preliminary reports^{1,2}, mammalian fibres from rabbit³ and rat^{4,5} have recently been successfully studied in detail by means of the voltage clamp. The early transient or sodium conductance system was found to be similar to that in frog and squid axons. However, the delayed conductance or potassium currents were found to be negligible^{4,6}. Only after chemical and osmotic manipulations, which were said to expose channels buried under the myelin, did Chiu and Ritchie⁷ find delayed currents in rabbit fibres. If confirmed, this would mean that the membrane conductance system of mammalian fibres is so different from that of invertebrate and amphibian axon models as to make the data base gathered from amphibian myelinated fibres (frog and toad) and invertebrate giant axons (squid and myxocolla) irrelevant to human and other mammalian fibres. However, we show here that it is possible to find in the normal nodal membrane of rat myelinated fibres potassium currents that flow through channels which are similar in many respects to those found in the frog node or squid axons.

Single myelinated motor fibres isolated from the sciatic nerve of rats were voltage clamped following the procedure of, and using the basic apparatus described by Nonner⁸. The voltage

clamp command potentials as well as the membrane current sampling rates were under digital computer (NOVA 800) control⁹. Holding potential (V_H) was adjusted to give a 70% sodium conductance inactivation. Membrane potential (V_M), which was defined at the end of each experiment by destroying the nodal membrane, averaged -78 ± 5 (s.d.) mV in 13 preparations. All currents were corrected for leakage (I_L) by computing the leak conductance from the inward currents elicited by membrane hyperpolarization. It was assumed that the leakage current–voltage relationship is linear and that $I_L = 0$ at the resting potential. The node was externally perfused with mammalian Ringer's solution. Potassium currents were measured in the presence of 300 nM tetrodotoxin (TTX). The composition of the internal solution was controlled by diffusion through the fibre's ends which were cut 400–700 μm away from the node¹⁰. Currents were converted to densities (mA cm^{-2}) assuming the nodal area to be 50 μm^2 (ref. 9).

Current tracings obtained in TTX Ringer at normal holding potentials, V_H , are shown in the insert of Fig. 1a. The tracings show a large instantaneous outward current jump (I_{inst}) followed by a delayed current component. I_{inst} was measured by extrapolating (on semilogarithmic scale) the initial position of the current⁷ tracing, beyond the capacity transient, to zero time.

The instantaneous current shows a linear $I_{\text{inst}}-V$ relationship, while the steady-state current, $I_{\text{ss}}-V$ curve shows some rectification and is very similar to that of the frog node (Fig. 2). Note that following the relatively rapid increase of the current in the first 3 ms there is a steady slow increase in current. This additional slow activation can be best demonstrated by the change of slope of the $\log(I_{\infty} - I_L)$ versus t curve as seen in the insert of Fig. 3b. In the example given, the initial time constant, τ_n , is 0.53 ms (this value is obtained after 'peeling off' the second time constant) and the slower time constant, τ_s , is 1.36 ms. The corresponding single τ at $V_H = -71$ mV is 0.56 ms, that is, τ_n is not altered by depolarizing V_H . Shifting V_H in the hyperpolarizing direction ($V_H = -100$ mV) has very little effect on the instantaneous current and produces a 15% increase in the delayed currents (open symbols in Fig. 1a). However, a relatively small (9 mV) shift of V_H in the depolarizing direction has a marked effect on the current tracings (Fig. 1b): they become square and are thus similar to those described by Chiu *et al.*⁶ and Brismar⁴. The squaring of the current traces, which was completely reversible, results mainly from an increase of the I_{inst} values to approach those of the steady state (I_{ss}). I_{ss} remains unchanged for depolarizations up to +10 mV, beyond which the currents generated at $V_H = -71$ mV are reduced by 10–15%. Note, however, that most of this reduction is due to the disappearance of the slow activation (see Fig. 1b). This disappearance or inactivation of the slow process obviously also contributes to the 'squaring off' of the currents.

Figure 2 compares the steady-state $I_{\text{ss}}-V$ relationship in the frog and rat. The shape of the curves obtained by means of the same voltage-clamp setup and procedure is clearly very similar, although the frog curve shows more rectification.

Moreover, in both cases the zero-current voltage cross-over point is shifted from around rest in normal Ringer's towards zero in high external $[\text{K}^+]$, indicating that the current is carried mainly by K^+ ions. Note the difference between the effect of high $[\text{K}]_o$ on the two preparations: it increases the potassium conductance, g_K , by about 50% in the frog and reduces g_K by 30% in the rat. The assumption that K^+ ions are the main charge carriers in the delayed channels is strengthened by the fact that the axoplasm in our fibres was in equilibrium with isotonic KCl solution. Therefore, the only membrane permeable ions in the axoplasm must be K^+ and Cl^- (ref. 10). As the chloride concentration remained unchanged, the large shift of the reversal potential indicates that the chloride permeability is relatively low. This low chloride permeability which is also typical of the frog node¹¹, indicates that the outward currents we are dealing with must be mainly carried by K^+ ions.

As reported by Chiu⁶ and Brismar⁴, we also find that external tetraethylammonium (TEA) only partly attenuates I_{ss} even at

Fig. 1 Steady-state and instantaneous current-voltage relationships at various holding potentials (V_H). All currents corrected for leakage. Test solution: Ringer TTX. Temperature 20 °C. *a*, $\blacktriangle$, Steady-state currents at $V_H = -80$ mV. $\blacksquare$, Instantaneous currents at $V_H = -80$ mV. $\diamond$, Steady-state currents at $V_H = -100$ mV. $\circ$, Instantaneous currents at $V_H = -100$ mV. Inset illustrates the recorded membrane currents as a function of time for different depolarizing pulses. The potential increment between the pulses was 5 mV from 15 to 60 mV and 10 mV from 60 to 120 mV. Calibration: horizontal bar = 0.8 ms. *b*, $\triangle$, Steady-state currents at $V_H = -71$ mV. $\square$, Instantaneous currents at $V_H = -71$ mV. The interrupted line gives the instantaneous currents generated by the same fibre at $V_H = -80$ mV. Inset illustrates the recorded membrane currents as a function of time for different depolarizing pulses. The pulse amplitudes are the same at those of *a*, as is the time scale.

relatively high concentrations (10 mM TEA attenuates I_{ss} by only 30%). I_{inst} was practically unaffected by TEA.

Figure 3a illustrates the voltage dependency of the normalized delayed channel steady-state conductance parameter, n_{∞}^x , which was computed using the following relationship:

$$n_{\infty}^x = I_{ss} / \bar{g}_K (V_M - V_K) \quad (1)$$

where $\bar{g}_K$ is the maximal membrane potassium conductance, V_K is the delayed channel reversal potential and x is the power of n in the Hodgkin-Huxley axon model. It is seen that near the resting potential ($V_M = -60$ mV) the potassium conductance, as determined by n_{∞}^x , is far from zero for both $x = 4$ (circles) and $x = 1$ (triangles). This is in contrast to the frog node or squid, where for the experimentally determined $x = 4$, the potassium conductance is negligible (interrupted line). The relatively high potassium conductance at the resting potential is obviously consistent with the relatively large initial current jump 'squaring off' obtained here and by others⁴ on membrane depolarization. It is also consistent with the initial current decay observed on membrane hyperpolarization by Chiu *et al.*⁶, and confirmed in the present work. The rate of this decay conforms with the projected values of τ_n at these potentials.

On the basis of the above, we suspect that the conclusion of Chiu *et al.* that (in the rabbit) this decaying current is capacitive (I_C) may be wrong. Moreover, because $I_C = C_M [dV_M/dt]$ (ref. 12), as $C_M \neq 0$ one must conclude that in their experiment $dV_M/dt \neq 0$, that is, the membrane was not fully voltage clamped throughout the first 0.5–1 ms.

We cannot attribute the almost completely square currents recorded by Chiu⁶ in the rabbit, and Brismar⁴ in the rat, to the shifted n_{∞} curve alone. However, this shift together with a somewhat depolarized membrane, as suggested by Chiu *et al.* themselves, may explain the results. Within the above framework, we may interpret the appearance of potassium currents following the rather drastic chemical and osmotic treatments in the rabbit⁶ as being due to a shift in the relative holding potential and perhaps also to a modification of the slow potassium activation process.

To rule out the possibility that in our experiments the myelin was lifted from the axolemma at the internode, we measured the nodal electrical capacity using the triangular wave voltage-clamp method¹². The nodal capacitance was found to be about 2.7 pF, compatible with that of the frog node¹³. The capacity did not change by more than 10% during the V_H changes which

induced the potassium conductance changes. These small C_M changes in the rat are definitely incompatible with the apparent 10-fold C_M change reported in the rabbit by Chiu *et al.*⁷ on the basis of the transient inward current obtained during membrane hyperpolarization.

Fig. 2 Potassium current-voltage relationships measured from frog and rat nodes by means of the same voltage clamp. All currents corrected for leakage. Temperature 20 °C. $\blacksquare$, Potassium currents from rat node. Each symbol represents an average current value from six fibres $\pm$ s.d. To eliminate scatter of data due to 'g' effect (through, for example, variance in the number of channels) all currents of each fibre, were first normalized by multiplying each current value by the ratio of the current value at $V = 120$ mV to the average current value for all fibres at this potential. $\square$, Potassium currents from the frog node (*Rana ridibunda*). Each symbol represents an average current value from four fibres $\pm$ s.d. Current normalization was carried out as above. $\blacktriangle$, Potassium currents measured from a rat node when the external Ringer solution was replaced by an isotonic KCl solution. $\triangle$, Potassium currents from a frog (*Rana esculenta*) when the external potassium concentration was raised from 2.5 to 80 mM.

Fig. 3 Potassium conductance parameters in the rat node. Temperature 20°C. *a*, The normalized steady-state potassium conductance (fraction of open channels). ●, n_{∞}^x values calculated from equation (1) for $x = 4$. △, n_{∞}^x values calculated from equation (1) for $x = 1$. Interrupted line: normalized conductance or fraction of open channels in frogs ($x = 4$), after Hille¹⁴. Note that close to the resting potential, at $V = -60$ mV, the relative conductance of the rat is at least five times larger than that of the frog. *b*, The potassium conductance time constants, τ_n , versus membrane potential. The symbols represent four rat fibres. Solid line, the average τ_n . Interrupted line, τ_n values in frog taken after Hille¹⁴. Inset: the $\log [I_{\infty} - I_t]$ versus time (t) relationships for potassium currents at $V_H = -80$ mV (filled symbols) and $V_H = -71$ mV (open symbols). Note the double exponential at $V_H = -80$ mV, the disappearance of the second exponential when $V_H = -71$ mV and the similarity between the first exponential at -80 mV and the single exponential at -71 mV. Note also in Fig. 1*b* that beyond 2 ms the current traces for $V_H = -71$ mV become completely flat so that we could not continue the corresponding trace beyond this time.

Beyond the initial delay, the potassium currents show double exponential kinetics when plotted on a semilogarithmic scale (Fig. 3*b* inset). From the slopes of the initial exponential relationships we computed the potassium conductance time constant, τ_n . Figure 3*b* shows the voltage dependence of τ_n from four fibres. The shape of the curve and the absolute τ_n values are similar to those previously measured in frog¹⁴ (broken line) and in rabbit 'internode'⁶.

Thus, when compared with amphibian fibres, the delayed channels in the rat are characterized by the following features: (1) The n_{∞} - V_M curve is shifted towards more negative potentials, that is, at negative membrane potentials the n_{∞} values are much higher than the corresponding values in the frog and squid. This fact is responsible for the much larger conductances near the resting potential and as a consequence a large initial outward current step on depolarization. Many of the special properties of the potassium system in the rat, such as the current decay on membrane hyperpolarization, are probably due to this fact. (2) The values and voltage dependence of the initial time constant of the change in potassium conductance, τ_n , are very similar to the corresponding parameters in frog. This parameter is not affected by depolarizing V_H . (3) The initial increase in I_K , obtained on membrane depolarization, is followed by a smaller and slower increase or activation. The time constant of this slower activation process is about three times larger than the initial ' τ_n ' value. (4) Prolonged small membrane depolarizations (5–10 mV) attenuate steady-state I_K by 10–15% mainly by reducing the amplitude of the slow activation to virtually zero. The time constant of the development of this inhibition is >20 ms. Prolonged membrane hyperpolarizations increase steady-state I_K by 10–20%.

On the basis of the above findings, we believe that the excitability properties (threshold, action potential, refractoriness) of mammalian fibres in normal conditions can be analysed and reconstructed on the basis of models, similar in principle but modified in some details, with regard to the potassium system, to those developed for the frog and squid.

This study was performed in partial fulfillment of the requirements of the D.Sc. degree for O.B.

Prolactin inhibits oestrogen synthesis in the ovary

Jennifer Dorrington & Robert E. Gore-Langton

Banting and Best Department of Medical Research,
University of Toronto, Toronto, Ontario, Canada M5G 1L6

In 20% of cases of secondary amenorrhoea, hyperprolactinaemia prevents ovulation by impairing normal follicular development, but little is known of the biochemical basis for this effect¹. Bromocriptine can restore follicular growth and ovulation² by inhibiting the release of prolactin from the pituitary. The suckling stimulus causes an increase in prolactin levels³, and ovarian follicles fail to develop fully, thus inducing an anovulatory state throughout lactation in many mammals. We report here experiments with cultured granulosa cells which suggest that this contraceptive action of prolactin is due to its ability to interfere with the action of follicle-stimulating hormone (FSH) on the synthesis of oestrogen.

Fig. 1 Effect of FSH and prolactin on the aromatase activity of ovarian granulosa cells, assessed by the release of $^3\text{H}_2\text{O}$ from $[1\beta\text{-}^3\text{H}]$ testosterone. Granulosa cells were obtained from 25-day-old rats which had been treated daily for 3 days with 1 mg diethylstilboestrol in sesame oil. The cells were plated in Falcon 24-well tissue culture plates so that each well contained 100 μg protein and 0.5 ml modified Eagle's minimum essential medium, and were maintained at 37 °C in a water-saturated atmosphere of 95% air and 5% CO_2 . Cells were treated with 300 ng NIH-FSH-S13 ml^{-1} and/or 1 μg NIH-P-S-7 ovine prolactin ml^{-1} 2 h after plating; the medium was changed after 24 and 48 h and appropriate treatments repeated. At 24, 48 and 72 h, 0.1 μCi $[1\beta\text{-}^3\text{H}]$ testosterone, containing unlabelled testosterone to give a final concentration of 0.25 μM , was added to four replicate cultures from each treatment group (C, controls; PRL, prolactin-treated; FSH, FSH-treated; FSH+PRL, FSH and prolactin-treated). The cells were incubated for 2 h at 37 °C and the reaction stopped by placing the plates on ice. The medium was transferred to tubes and Norit A-activated charcoal (25 mg in 100 μl H_2O) was added. Incubations with charcoal for 2 h at 0 °C completely adsorbed steroids without influencing the recovery of tritiated water. Steroids adsorbed to charcoal were removed by centrifuging at 4,000 r.p.m. and 4 °C for 30 min. An aliquot (0.5 ml) of the supernatant was counted in 5 ml Aquasol.

The aromatization of the androgens, androstenedione and testosterone, to oestrogens in the ovarian granulosa cells, under the influence of FSH, involves a series of closely integrated reactions catalysed by an enzyme complex referred to as 'aromatase'⁴. To assess the aromatase activity of granulosa cells after various hormone treatments, the stereospecific release of $^3\text{H}_2\text{O}$ from $[1\beta\text{-}^3\text{H}]$ testosterone was measured—this assay has been validated as a specific measure of aromatization in granulosa cells⁵. Treatment of the cells with FSH shortly after plating in culture resulted in elevated aromatase activity after 24 h of treatment and a further increase after 48 and 72 h of treatment (Fig. 1). This effect of FSH confirmed earlier indications that it was involved in activating the aromatase system in immature granulosa cells, an important step leading to the formation of the preovulatory follicle⁶.

To investigate whether prolactin can influence this effect of FSH, prolactin was added alone, or together with FSH, to cultured cells. The amount of $^3\text{H}_2\text{O}$ released by the cell monolayers during a 2-h incubation with $[1\beta\text{-}^3\text{H}]$ testosterone was measured after 24, 48 and 72 h of treatment. Prolactin did not affect FSH-induced aromatase activity for the first 24 h of treatment, but between 24 and 48 h it inhibited the effect of FSH; this suppressed level of activity was also observed after 72 h (Fig. 1). In other experiments, concentrations of prolactin

Fig. 2 Effects of FSH and prolactin on the aromatase activity of sonicates of ovarian granulosa cells using an optimal cell-free assay. Granulosa cells were prepared from diethylstilboestrol-primed immature rats and were cultured in 35 × 15 mm culture dishes in 1 ml Eagle's minimum essential medium for 48 (a) or 72 (b) h in the presence or absence of 300 ng NIH-FSH-S13 ml^{-1} and/or 1 μg NIH-P-S-7 ovine prolactin ml^{-1} . Medium was changed and treatments repeated after each 24-h culture period. At 48 and 72 h, cultures from each treatment group were washed, cells were scraped from the plates and transferred to tubes in 20 mM phosphate buffer, pH 7.4. The cell suspensions were sonicated on ice and 0.2-ml aliquots of the sonicates dispensed into assay tubes containing the following reagents: 0.1 ml of 20 mM phosphate buffer; 0.1 ml of buffer containing MgCl_2 and dithiothreitol to give a final concentration of 20 mM and 5 mM respectively; 50 μl NADPH generator (final concentration of NADP, 0.5 mM; glucose-6-phosphate, 20 mM; and glucose-6-phosphate dehydrogenase, 2U ml^{-1}); and 0.05 ml testosterone solution containing 0.4 μCi $[1\beta\text{-}^3\text{H}]$ testosterone and unlabelled testosterone to give a final concentration of 0.25 μM . Incubations with gentle shaking were for 1 h at 37 °C in an atmosphere of 95% O_2 and 5% CO_2 . The reaction was stopped by cooling tubes in ice-water and adding Norit A-activated charcoal (25 mg in 0.1 ml H_2O) to adsorb the steroids. Aliquots of the supernatant were counted in 5 ml Aquasol. Data are the means $\pm$ s.e.m. ($n = 3$).

from 10 to 100 ng ml^{-1} also inhibited the FSH-induced response. These concentrations are within the physiological range found in human follicular fluid⁷. No effects of prolactin alone were detectable during 72 h of culture, but this was not surprising as undifferentiated granulosa cells from immature animals do not contain specific prolactin binding sites⁸. Wang *et al.*⁹ showed that FSH stimulated the appearance of specific prolactin receptor sites on granulosa cells *in vitro* which may explain the 24-h lag before the effects of prolactin on FSH-induced aromatase activity were apparent.

To eliminate the possibility that prolactin influences aromatase activity by restricting the permeability of substrate or the availability of co-factors to the enzyme system, cells in culture were treated with hormones for various periods, after which cell sonicates were prepared and aromatase activity measured in the cell-free system in optimal conditions. As before⁵, pretreatment of granulosa cells in culture with FSH increased aromatase activity in the cell-free preparations (Fig. 2). Prolactin effectively reduced the amount of active aromatase induced by FSH during the first 48 h of culture and this effect increased after 72 h of treatment. Incubation of cell sonicates in optimal conditions showed that FSH and prolactin influenced aromatase activity in cultured granulosa cells by mechanisms which were independent of effects on the availability of substrate and

co-factor. FSH acts on granulosa cells to increase the amount of active aromatase, and prolactin seems to interfere with the ability of FSH to bring about this effect.

In addition to inhibiting FSH-induced oestrogen biosynthesis in rat granulosa cells, prolactin ($50\text{--}1,000\text{ ng ml}^{-1}$) affects steroidogenesis by stimulating progesterone synthesis⁹; the mechanism of two such different responses is intriguing. However, in human granulosa cells, high levels of prolactin seem to inhibit progesterone production¹⁰, and divergent effects have been demonstrated in porcine granulosa cells depending on the degree of differentiation¹¹.

When prolactin levels are high due to physiological (for example, lactation) or pathological (for example, hyperprolactinaemia) conditions, the inhibition of oestrogen biosynthesis and the concomitant changes in progesterone biosynthesis may establish a microenvironment in which the follicles can no longer develop normally and ovulation is suppressed¹.

α -Lactalbumin is not a marker of human hormone-dependent breast cancer

Len Hall, Roger K. Craig*, Michael S. Davies,
David N. L. Ralphs & Peter N. Campbell

Courtauld Institute of Biochemistry, and the Department of Surgical Studies, The Middlesex Hospital Medical School, London W1P 7PN, UK

It has been proposed that milk protein gene expression in human breast carcinomas may indicate a functional oestrogen receptor mechanism, and may therefore be diagnostic of tumours responsive to endocrine therapy¹. Unfortunately this has not been proved, largely because of inconsistencies in the immunoassay procedures used to identify milk proteins, in particular α -lactalbumin, in tissue extracts or serum^{1–12}. Alternative procedures include the identification of milk protein mRNA by cell-free protein synthesis¹³, and the identification of milk protein RNA transcripts by hybridization to a sequence-specific probe. Here we describe experiments using α -lactalbumin cDNA probes, purified using recombinant plasmids¹⁴, which demonstrate that although polyadenylated and non-polyadenylated α -lactalbumin transcripts are present in normal human mammary tissue during pregnancy and lactation, α -lactalbumin transcripts are not detectable in the human tumour tissues studied. These experiments do however show that a peptide, which shares antigenic determinants with human α -lactalbumin is present in some breast tumour tissues.

Human and guinea pig α -lactalbumin cDNA hybridization probes were used in RNA excess hybridization studies to compare the relative amounts of human α -lactalbumin RNA transcripts in different RNA preparations. Guinea pig α -lactalbumin cDNA, which fortuitously has extensive sequence homology with the human α -lactalbumin cDNA¹⁴, was also used as only limited amounts of human milk protein mRNA were available for production of cDNA probes. As can be seen in Fig. 1, >60% of guinea pig α -lactalbumin cDNA was protected from S_1 nuclease digestion when hybridized with poly(A)-containing RNA from lactating human mammary tissue 15 days post partum¹³. Furthermore, the kinetics of hybridization were identical to those of the homologous hybridization using human α -lactalbumin cDNA. Analysis of poly(A)-containing RNA

Fig. 1 Abundance of human α -lactalbumin transcripts in polyadenylated and non-polyadenylated RNA fractions isolated from normal mammary tissues of lactating and pregnant patients. Poly(A)-containing RNA was isolated from frozen human mammary tissue¹³ and hybridized either to human or guinea pig α -lactalbumin-specific cDNA as described elsewhere¹⁴. Non-polyadenylated RNA was defined as that which did not bind to oligo (dT)-cellulose at a salt concentration of 100 mM (ref. 15). The volume of individual hybridization assays (up to 100 μ l) and the RNA concentration (up to 5 mg ml⁻¹) were increased where appropriate to ensure an adequate RNA excess. Human α -lactalbumin cDNA versus poly(A)-containing RNA from 15-day post partum lactating human mammary tissue (x); guinea pig α -lactalbumin cDNA versus poly(A)-containing RNA from 15-d (●), 4-d (▲) and 330-d (▼) post partum mammary tissues, and normal breast tissue from a patient 32 weeks into pregnancy (■); guinea pig α -lactalbumin cDNA versus non-polyadenylated RNA from 15-d (○), 4-d (△) and 330-d (▽) post partum and 32-week pregnant (□) mammary tissue. The dashed line represents the homologous hybridization kinetics of highly purified rabbit globin mRNA standard¹⁴.

populations isolated from normal lactating mammary tissue 4 and 330 days post partum, and normal mammary tissue 32 weeks into pregnancy, using the guinea pig cDNA probe, demonstrated the presence of α -lactalbumin mRNA in each preparation but at different concentrations (Fig. 1). Compared with the 15-day post partum population, α -lactalbumin transcripts were present at 1.5-fold, 4-fold and 30-fold lower concentrations in the 4-day post partum, 330-day post partum and pregnant tissues, respectively. Analysis of the non-polyadenylated RNA from each tissue (RNA that did not bind to oligo (dT)-cellulose and contained polyadenylic acid tracts <35 nucleotides long¹⁵) showed that α -lactalbumin transcripts were present in all the preparations examined, again at different relative concentrations (Fig. 1). The overall analysis of normal human mammary tissue demonstrates that in common with the rat^{16,17}, mouse^{18,19} and guinea pig²⁰, α -lactalbumin gene

expression occurs in the mammary gland before parturition as well as throughout lactation. In common with many mRNA species including other milk protein mRNAs, human α -lactalbumin mRNA is distributed between the polyadenylated and non-polyadenylated RNA populations¹⁵.

Similar examination of polyadenylated and non-polyadenylated RNA populations isolated from human mammary tumours produced unexpected results. Poly(A)-containing RNA was isolated from 12 breast tumours (including adenocarcinomas, infiltrating duct carcinomas and a benign tumour): six were examined using a human cDNA probe, one of which, designated T2, an invasive duct carcinoma, had previously been shown to synthesize α -lactalbumin as determined by a combination of mRNA-directed cell-free protein synthesis, antibody precipitation and SDS-polyacrylamide gel electrophoresis¹³. However, hybridization studies (Fig. 2a) showed that none contained α -lactalbumin transcripts as there was only limited hybridization when compared with controls (chick oviduct and human placental poly(A)-containing RNA). The remaining six, which were analysed using the guinea pig cDNA probe, also contained no α -lactalbumin transcripts (Fig. 2b), even though three of these tumours had been independently shown by radioimmunoassay to contain significant amounts of α -lactalbumin (1,029, 716 and 1,554 pg per mg protein). Two of those containing α -lactalbumin as determined by radioimmunoassay also had elevated levels of oestrogen and progesterone receptors. Analysis of the non-polyadenylated RNA

Fig. 2 Hybridization of poly(A)-containing RNA from human breast tumours to α -lactalbumin cDNA. Poly(A)-containing RNA was isolated from 12 frozen breast tumours¹³: six of these were challenged with (a), human α -lactalbumin cDNA and six with guinea pig α -lactalbumin cDNA (b). In each case the range of values obtained is indicated by error bars. Dotted lines represent the hybridization of poly(A)-containing RNA from 15-d postpartum lactating breast tissue to human (a) and guinea pig (b) α -lactalbumin cDNAs. Negative and positive controls were: (O), human α -lactalbumin cDNA versus human poly(A)-containing placental RNA; Δ , guinea pig α -lactalbumin cDNA versus a mixture of poly(A)-containing RNA from tumour and lactating tissue (99:1), respectively.

Fig. 3 Hybridization of poly(A)-containing and total cellular RNA from established tumour cell lines of human mammary origin, to α -lactalbumin cDNA. Twenty 9-cm-diameter dishes of semiconfluent cells were washed briefly with phosphate-buffered saline then lysed *in situ* with 10 mM Tris-HCl, pH 7.6, containing 1 mM EDTA, 2% (w/v) SDS, 0.5 mg ml⁻¹ proteinase K (1 ml per plate). The lysates were then processed as described for frozen tissue¹³. a, Human α -lactalbumin cDNA versus poly(A)-containing RNA from MCF-7 cells (both early and late passages, with and without added oestrogen²⁵), Hs578T cells and T-47D cells; error bars indicate range of values obtained. b, Guinea pig α -lactalbumin cDNA versus total cellular RNA from the above cell lines. Dotted lines represent the hybridization of poly(A)-containing RNA from 15-d postpartum lactating breast tissue to human (a) and guinea pig (b) α -lactalbumin cDNAs; Δ , guinea pig α -lactalbumin cDNA versus a mixture of MCF-7 total cellular RNA and polyadenylated RNA from 15-d postpartum lactating tissue (10,000:1).

from eight of the twelve tumours studied, including all those supposedly synthesizing α -lactalbumin, also proved to be negative (results not shown). As a positive control, poly(A)-containing RNA from 15-day lactating human tissue¹³ was mixed with a 100-fold excess of poly(A)-containing RNA from tumour tissue, then hybridized to guinea pig α -lactalbumin cDNA. This resulted in maximum hybridization (Fig. 2b) with the expected shift of hybridization kinetics (two logarithmic decades). It is unlikely that the absence of α -lactalbumin transcripts in tumour RNA preparations reflects degradation during extraction, as we estimated the mean size of the poly(A)-containing RNA to be 1,250 nucleotides in denaturing conditions, while cDNA prepared from the same RNA populations was of the same size, as determined by agarose gel electrophoresis in denaturing conditions.

We also analysed human cell lines of mammary origin: Hs578T²¹, T-47D²² and MCF-7²³ cell lines, all of which have been reported to synthesize either casein or α -lactalbumin²⁴. We found no evidence for the presence of α -lactalbumin transcripts, whether human α -lactalbumin cDNA was hybridized to poly(A)-containing RNA preparations (Fig. 3a) or whether guinea pig α -lactalbumin cDNA was hybridized to total cellular RNA (Fig. 3b). In the case of the MCF-7 cell line, RNA was analysed from early(15)- and late(275)-passage cells, and from cells stimulated with oestrogen²⁵, with negative results. As a

positive control, poly(A)-containing RNA from 15-day post partum lactating human mammary tissue was mixed with a 10,000-fold excess of MCF-7 total cellular RNA. This produced the expected degree of hybridization and shift in kinetics (Fig. 3b), thus confirming the specificity of the assay.

Overall it is apparent that α -lactalbumin gene expression does not occur to a measurable extent in any of the tumours or cell lines examined, using hybridization procedures which can detect as little as one polyadenylated, or <10 non-polyadenylated RNA transcripts per cell. The absence of α -lactalbumin RNA transcripts in the cell lines was not surprising, because although preliminary *R₀t* analysis and Southern blotting of cell-line and human placental restricted DNA demonstrated that the genes were present, we had been unable to demonstrate the presence of α -lactalbumin mRNA by cell-free protein synthesis (L.H. and R.K.C., unpublished data). However, the absence of α -lactalbumin transcripts from tumour tissue was unexpected, particularly as we have previously reported that a peptide with the expected electrophoretic mobility of pre- α -lactalbumin¹³ was synthesized in a cell-free protein synthesizing system directed by a tumour mRNA preparation, and that this peptide could be preferentially precipitated by α -lactalbumin antisera. This particular observation has proved reproducible using the same tumour (T2) mRNA and our own or an alternative source of α -lactalbumin antiserum. Because no α -lactalbumin mRNA was present in this tumour mRNA preparation, we conclude that both α -lactalbumin antisera preparations were reacting with a peptide which not only shared antigenic determinants with α -lactalbumin, but was also of the same apparent molecular weight as pre- α -lactalbumin.

Although we have not established the precise nature of the peptide(s) precipitated by antiserum to human α -lactalbumin, we consider that the close correlation between ' α -lactalbumin' and oestrogen receptors, reported to indicate a functional oestrogen receptor mechanism¹, may still prove useful once this peptide has been identified. Consequently we are screening our library of human mammary cDNA plasmids for those plasmids containing sequences that are abundant in tumour mRNA populations, several recombinants are being studied. Thus although the results are negative from a clinical point of view, we have demonstrated that sequence-specific cDNA hybridization probes generated using recombinant DNA techniques may soon be important as diagnostic tools in medicine. To conclude, using highly sensitive and specific hybridization techniques, we found no evidence to support the concept that α -lactalbumin will prove to be a general marker for human hormone-dependent breast cancer.

We thank the Cancer Research Campaign for supporting this work and Dr A. Howell and his colleagues for performing the α -lactalbumin radioimmunoassay, the hormone receptor analyses, and providing an alternative source of human α -lactalbumin antisera. Avian myeloblastosis virus reverse transcriptase was provided by Drs J. Beard and J. Gruber. Human mammary cell lines Hs578T and T-47D, and early- and late-passage MCF-7 cell lines were given by Drs Adeline Hackett, I. Keydar and C. McGrath, respectively.

Enhanced frequency of chromosome aberrations in lymphocytes of male compared with female muntjacs after X-ray irradiation *in vitro*

B. C. Das & T. Sharma

Cytogenetics Laboratory, Department of Zoology, Banaras Hindu University, Varanasi-221005, India

Recently, there has been considerable interest in the study of radiation-induced dicentrics and other chromosome aberrations in phytohaemagglutinin (PHA)-stimulated blood lymphocytes of various mammals, including man, with the aim of establishing a proper biological dosimetry for the assessment of genetic radiation hazards in human. These studies have revealed that the radiosensitivity of lymphocytes differs between species and even between individuals of the same species¹⁻⁵, but the cause(s) of these variations still remains unclear. The life-shortening response to whole-body X-ray irradiation is influenced by both age and sex of the individuals⁶⁻⁹, but although age has been shown to have effects on chromosome aberration yields^{4,10-12} *in vitro*, the influence of sex on the sensitivity of lymphocyte chromosomes to radiation-induced damage has not been reported. It is generally thought that sex does not influence the aberration yield within the limitation of measurements used in such studies. However, we report here a study of X-ray induced chromosome aberration in lymphocytes of Indian muntjac, in which the yield of dicentrics was found to be consistently greater in male than in female lymphocytes.

We prepared lymphocyte cultures from healthy, young adult muntjacs (*Muntiacus muntjak*) selected from a small breeding colony which we maintained. The specimens were chosen so that we could do experiments on blood samples of three pairs of muntjacs of similar age and body weight. This barking deer has only six chromosomes in the female, with XX sex chromosomes, and seven in the male, with XY₁Y₂ sex chromosomes^{13,14}, and both the complements are distinguishable from each other by distinct constitution and morphology of the sex chromosomes (Fig. 1 a-d). This unique sex-based karyotypic dimorphism was used in a 'mixed blood culture' (MBC) method where whole blood drawn from males and females was mixed in equal proportion and then irradiated with various doses of X rays (110 kV, 4 mA, 1 mm Al and 100 rad min⁻¹ at 37°C) and cultured. This method ensures greater accuracy as it eliminates the possibility of errors inherent in irradiating and growing cultures separately for male and female individuals. The frequent metaphases for both sexes in MBCs, and the relative frequencies of first-, second- and third-division cells obtained at different times of fixation from male and female blood cultures set up separately, or after mixing, indicated that the normal progression of cell division had no obvious 'cross-reaction' in the MBCs. The results will be published in detail elsewhere.

A low concentration (0.1 µg ml⁻¹) of 5-bromodeoxyuridine (BUdR)¹⁵ was added at the start of culture and the chromosome preparations were stained using the Hoechst-sunlight-Giemsa technique^{16,17} to score aberrations only from the first-cycle

Fig. 1 Metaphase chromosomes of male and female muntjacs. *a*, First-cycle and *b*, second-cycle metaphase preparations from female muntjac lymphocytes showing six chromosomes with XX. *c*, First-cycle and *d*, second-cycle metaphase preparations from male muntjac lymphocytes showing seven chromosomes with XY_1Y_2 , a multiple sex chromosome system due to X-autosome translocation.

metaphases^{3,18-21}. For multiple sampling, fixation was done at 32 and 40 h to analyse aberrations. The frequencies of dicentric and other chromosome aberrations were scored from coded slides from 50–100 first-cycle male and female metaphases. The frequency of sister chromatid exchanges (SCEs) was scored from second-cycle metaphases and the experiments were repeated two to three times for each pair of muntjac.

The results obtained from the MBCs fixed at 32 h (Table 1) and 40 h (Table 2) as well as from the cultures of male and female lymphocytes set up separately (Table 3) indicated that the male lymphocytes were consistently more radiosensitive than female lymphocytes, as they showed a significantly higher (1.86 ± 0.25 , $P < 0.01$ or 0.05) frequency of dicentric (Fig. 2). Although the frequency of deletions, which did not include fragments associated with dicentric and rings, was quite high and at times showed significant variation between the two sexes, the frequency was not significantly different in most cases. With regard to symmetrical exchanges, there was sometimes a slight increase in the yield in females but the frequency was found to be statistically insignificant when compared with yields in males. The analysis was not done after banding of chromosomes, therefore their frequencies are not very precise the data on symmetrical translocations have not been shown. The yield of dicentric in cultures set up separately for male and female was slightly lower than in the MBCs (Fig. 2) but the magnitude of difference in the yield of dicentric between the two sexes still

Fig. 2 Dose-response curves for dicentric in male and female muntjac lymphocytes grown in MBCs (●, male; ▲, female) and separately (○, ♂ male; △, ♀ female), after exposure to various doses of X rays. The curves are the least-squares regression lines of $y = a + bD$ ($r = 0.98$, $P < 0.001$).

remained the same. The frequency of other chromosome aberrations (Tables 1, 2, 3) however, did not show any significant difference between the two sexes, either in the MBCs or in the separate cultures. The frequency of SCEs was the same in male and female lymphocytes and was of the order of those occurring spontaneously, even after exposure to 400 rad (Table 4). This corroborates the suggestion that the mechanisms of production of SCEs and chromosome aberrations are different²⁰⁻²³.

Our previous study¹⁸ using the BUdR-harlequin technique on male muntjac lymphocytes fixed at 40 and 48 h after X-ray irradiation and initiation of cultures, and the present study of MBCs fixed at 32 and 40 h (Tables 1, 2) gave similar yields of dicentric and rings in the first-cycle metaphases. This strongly suggests homogeneous sensitivity of muntjac lymphocytes to X-ray irradiation, which has also been reported for humans^{3,21}. Nevertheless, there are reports on human lymphocytes which suggest the presence of at least two subpopulations that differ in rate of progression of cell cycle and radiosensitivity^{20,24,25}. In view of the conflicting reports on human lymphocyte radiosensitivity, we scored dicentric in lymphocytes of both sexes of muntjac only from the first wave of mitosis, mainly at 32 h, even though the yield of metaphases was very low at this hour, particularly in the case of male metaphases.

The significant difference observed in the frequency of X-ray induced dicentric therefore indicates differential radiosensitivity of lymphocytes in the two sexes of muntjac. The low number of chromosomes in muntjac may suffer from 'distortion' in radiation-induced chromosome exchange analysis²⁶ but the slight difference in the chromosome number of males and females of muntjac is not expected to influence the yield of dicentric in the two sexes. Thus these results reflect a real difference in radiosensitivity. Differential repair efficiency and/or other intrinsic factors may be responsible for this differential sensitivity. It is, however, interesting to note that in

Table 4 Sister chromatid exchange (SCE) frequency in control and irradiated cultures of male and female muntjac lymphocytes

X-ray dose (rad)	Sex	Total metaphases scored	Total SCEs scored	SCEs per cell $\pm$ s.e.
0	Male	50	363	7.26 ± 0.46
	Female	50	365	7.30 ± 0.42
100	Male	50	382	7.64 ± 0.72
	Female	50	448	8.96 ± 1.37
200	Male	50	341	6.82 ± 0.29
	Female	50	325	6.50 ± 0.59
400	Male	50	362	7.24 ± 0.39
	Female	50	382	7.64 ± 0.82

Down's syndrome, the presence of an extra chromosome 21 has been shown to cause a 50–100% increase in the incidence of radiation-induced exchange-type aberrations (dicentric and rings), whereas the frequencies of breaks and other intra-chromosomal changes are not affected^{10,11,27}. Although the situation is not parallel, we could assume that the presence of Y in male muntjac as an extra chromosome in the complement in some way accounts for the higher yield of dicentric. Experiments on other species with similar sex chromosome constitution, resulting in a difference in chromosome number between the two sexes, may elucidate this point.

We thank Professor J. R. K. Savage for help with the manuscript, and Drs H. Loewe and V. V. Menon for the gift of Hoechst 33258 and statistical advice, respectively. The work was supported by grants from the International Atomic Energy Agency, contract nos 2126/RB and 2126/RI/RB and the University Grants Commission, India.

Altered ribosomal RNA genes in mitochondria from mammalian cells with chloramphenicol resistance

Stephen E. Kearsey & Ian W. Craig

Genetics Laboratory, Department of Biochemistry,
University of Oxford, Oxford OX1 3QU, UK

Chloramphenicol resistance in mammalian cells is cytoplasmically inherited^{1,2}. In yeast, a similar phenotype is caused by mutations in the mitochondrial DNA (mtDNA), and sequencing of carefully constructed strains has identified nucleotide monosubstitutions in the 3' region of the large (21S) rRNA gene which correlate with the antibiotic resistance³. We have sequenced the corresponding section of mammalian mtDNA from chloramphenicol-resistant cell lines for comparison with the wild-type sequence. Differences between the sequences occur at positions similar to those altered in the yeast mutants, in a highly conserved region of the large (16S) rRNA gene.

The chloramphenicol-resistant cell lines investigated were 3T3CAP^R (ref. 4 and R. L. Siegel, unpublished data) derived from the mouse cell line 3T3, and the human line MC63 derived from HeLa B (ref. 5). Cytoplasm-cell fusion experiments have shown convincingly that the chloramphenicol resistance of these

Fig. 1 The positions of *Bam*HI, *Eco*RI and *Hind*III restriction enzyme sites in mouse mtDNA²⁰; O denotes the H-strand replication origin, and the direction of transcription of the rRNA genes is marked²¹. The *Bam*HI-A fragment was purified by cloning in pBR322 (ref. 7), and the smaller *Bam*HI-*Eco*RI subfragment was isolated and digested with *Sau*3A. This was ligated into the double-stranded form (RFI) of a bacteriophage M13mp2 derivative adapted to accept *Bam*HI fragments^{9–11} (amber mutation in phage; G. Winter, unpublished results). Recombinant phage, which give colourless plaques on a lawn of *E. coli* JM101 (ref. 22), were grown up for screening as described in the text. The universal primer from pSP14 (ref. 23) was used for dideoxy sequencing¹⁴.

cell lines may be cytoplasmically transmitted to sensitive cells^{2,6}, although further genetic characterization has not been completed.

MtDNA from 3T3CAP^R cells was cloned as *Bam*HI restriction fragments using the plasmid pBR322 (Fig. 1 and ref. 7). Similar banks were also made using mtDNA from the parental cell line 3T3 and mouse liver. Plasmids containing the *Bam*HI-A fragment were prepared, allowing the purification of the smaller (1.3-kilobase) *Eco*RI-*Bam*HI subfragment from the plasmid insert. This contains the 3' end of the large (16S) rRNA gene (Fig. 1). The fragment was cut multiply with *Sau*3A for subcloning, using a bacteriophage M13mp2 derivative as vector^{8–10}.

Recombinant M13 clones from the mouse liver mtDNA bank were screened by partial sequencing reactions, using one dideoxynucleotide, ddT¹¹. Clones chosen for detailed sequence analysis were those containing restriction fragments having homology with the yeast 21S rRNA gene region in which nucleotide changes conferring chloramphenicol resistance are found³. As human and mouse mtDNA show high sequence homology in the rRNA genes¹², this screening was made easier by aligning the human 16S rRNA gene sequence¹³ with the yeast sequence. Comparison of the thymidine partial sequences of the mouse *Sau*3A fragments with the human sequence allowed the identification of several hybrid phage containing a 92-base pair fragment which spans the relevant region of the 16S rRNA gene. Two of these clones, containing this fragment in opposite orientations, were used to select clones from the 3T3 and 3T3CAP^R banks for dideoxy sequencing¹⁴. In this hybridization screening¹⁵, single-stranded DNA from clones containing the same restriction fragment as the reference clone, but in an opposite orientation, formed a hybrid with the reference clone DNA. These DNA hybrids have a lower mobility on agarose gels than the non-annealed single strands.

The MC63 mtDNA was digested with *Sau*3A and cloned directly into bacteriophage M13. Hybridization screening of 40 recombinant phages identified three homologous clones which were used for sequence determination.

Comparison of the mtDNA sequences obtained shows that the 92-base pair *Sau*3A fragments from 3T3CAP^R and 3T3 mtDNA differ by one nucleotide at position 30 (Fig. 2).

Fig. 2 Comparison of the DNA sequences in the 3' region of the large rRNA genes, showing positions of nucleotide changes in mtDNA from chloramphenicol-resistant cells. Sequences of the noncoding strand are given. The sequences compared are from human (placental) mtDNA¹³, mouse (3T3 or liver) mtDNA, yeast (*Saccharomyces cerevisiae* strain 1L9-8A/D122, with the C₃₂₃ site in its wild-type configuration) mtDNA³ and *E. coli* (*rrnB* gene)¹⁶. The sequences are aligned to show major blocks of homology, with gaps where appropriate. Asterisks show identity between adjacent sequences and boxed-in regions indicate sequences conserved between all four. Underlining indicates the position of the stem of a hairpin loop structure which is conserved between all four sequences. Nucleotide monosubstitutions in mtDNA sequences from chloramphenicol-resistant cells are indicated as follows: 1, MC63 (T to C); 2, 3T3CAP^R (A to T); 3, C₃₂₃ mutation in yeast (G to A)³; and 4, C₃₂₁ mutation in yeast (A to C)³.

Comparison with the yeast sequence data shows that this A-T transversion is only four nucleotides away from a homologous site at which a G-A transition in the *rib-1-B* locus causes the chloramphenicol resistance mutation C₃₂₃^R (ref. 3). This suggests that the sequence alteration is responsible for the antibiotic resistance phenotype of 3T3CAP^R although no functional genetic test is available. It is less likely that this mutation represents a silent polymorphism as the wild-type sequence compared is from the parental cell line. In any case, there are no differences between the 3T3 and mouse liver sequences (see Fig. 2) which suggests that polymorphism in the 3' region of the 16S rRNA gene is not high, and that the cloning steps used do not mutate the original nucleotide sequences.

The 104-base pair *Sau3A* fragment from MC63 mtDNA also shows one difference compared with the human placental sequence reported by Eperon *et al.*¹³ (Fig. 2). This monosubstitution, a T-C transition at position 96, is one nucleotide away from a homologous site in yeast mtDNA where an A-C transversion at the *rib-1-A* locus causes the chloramphenicol resistance mutation C₃₂₁^R (ref. 3).

The single nucleotide changes in the mtDNA from both the mouse and human mutant cell lines occur in short sequence blocks which are identical in the yeast mitochondrial 18S rRNA gene and the *Escherichia coli* 23S rRNA (*rrnB*) gene (Fig. 2 and refs 3, 16). Such conservation probably reflects functional constraints imposed on this region of the genome and suggests that a small genetic change, such as a base pair alteration, could have a considerable effect on the cell phenotype. Furthermore, this evolutionary stability makes it less likely that irrelevant polymorphisms are being detected.

Structural studies of the *E. coli* ribosome indicate that in the rRNA, the sequence shown in Fig. 2 occurs at the interface between the 30S and 50S subunits, the RNA being protected from kethoxal modification on subunit association¹⁷. This agrees well with the high degree of sequence conservation of this region through evolution compared with other parts of the large rRNA¹³. The nucleotides which are altered in chloramphenicol-resistant mutants are probably implicated in binding the 3' terminus of aminoacyl tRNA, because chloramphenicol blocks

this site¹⁸. A hairpin loop can be constructed between the mutation sites, and this feature is conserved despite local divergence of the primary sequences compared in Fig. 2 (ref. 19). If this structure occurs in the ribosome it would bring the putative chloramphenicol-binding sites together.

Further sequence analysis of mtDNA from other chloramphenicol-resistant cell lines should help to confirm the correlation suggested here. Chloramphenicol resistance is the only readily obtainable genetic marker in the mammalian cytoplasm, and a simple molecular basis for the mutation might help to explain why this is the case.

We thank Greg Winter for the primer, and Elin Munro for culturing and phenotypic characterization of cell lines. This work was supported by grants from the CRC and the Christopher Welch Trustees.

MATTERS ARISING

Sexual dimorphism in early anthropoids

FLEAGLE *ET AL.*¹ provide an estimate of sexual dimorphism in extinct anthropoid primates based on a positive relationship between the degree of sexual dimorphism in body weight and the coefficient of variation (c.v.) of mandible depth in extant anthropoids. A cursory glance at Table 1 shows that their data on the degree of body weight dimorphism are incorrect. As a striking example, capuchin monkeys (*Cebus apella*) are supposedly more dimorphic than gorillas (*Gorilla gorilla*) which, as any visitor to the zoo knows, is simply not the case. Gorillas are far more dimorphic than capuchin monkeys.

A closer examination of the data reveals that 9 (those taken from our study on sexual dimorphism²) out of 13 species do not express a mean male weight/mean female weight ratio as intended by Fleagle *et al.*, but instead show a ratio between the cube roots of male and female weights. In our study we used the cube root of body weight to obtain a linear dimension comparable to a linear canine dimension. Using corrected data for body weight, I recalculated its correlation with the c.v. of mandible depth and obtained a correlation coefficient, $r = 0.597$, which is substantially lower than $r = 0.940$ as calculated by Fleagle *et al.* This leaves >60% of the variance unexplained, which in turn indicates that the coefficient of variation is a much poorer predictor of the degree of sexual dimorphism than they suggest. A solid quantitative method for estimating the degree of sexual dimorphism in fossils based on the variability within a species and independent of prior sex determination of individuals still eludes us.

2. Leutenegger, W. & Kelly, J. T. *Primates* **18**, 117–136 (1977).

FLEAGLE *ET AL.* REPLY—Leutenegger correctly points out that we inadvertently mixed the body size data in Table 1 of our paper¹ and therefore overestimated the correlation coefficient. In rechecking our original data, it turns out that we incorrectly transcribed the c.v. of mandibular depth for *Cebus apella* as well; the correct value is 14.5. When the

correlation coefficient for the entire sample was recalculated, using the cubed roots of body weight as suggested by Leutenegger, the correct value for r was 0.755. Although this value is lower than that previously reported, it is still highly significant ($P < 0.01$) and demonstrates a positive correlation between c.v. of mandible depth and sexual dimorphism in body weight. This correction in no way affects our major points: that the coefficient of variation for mandible depth and the amount of canine dimorphism in the Fayum anthropoids are considerably higher than that found in any of the monagamous taxa.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

Enzyme heterozygosity and morphological variance

HANDFORD¹ recently reported a lack of association between enzyme heterozygosity and measures of morphological

variance in the Rufous-collared sparrow. He suggested that this negative case, which was in apparent contrast to the findings of myself² and Mitton³, could be explained by an inherent difference, with regard to this relationship, between homoiotherms and poikilotherms. Although Handford makes several statistical points worth consideration, he ignores the fundamental problem of statistical power in his analysis. Essentially, his data set is so small that unless we assume the putative relationship between heterozygosity and morphological variability to be extremely strong, the ability to reject the null hypothesis of equal variances will be very restricted.

If enzyme heterozygosity does exert some influence on morphological variability, our biological intuition suggests that the contribution of individual loci will be subtle. Examination of the data sets for the monarch butterfly² and the killifish³ clearly support this notion. For example, the ratio of homozygote to heterozygote variances in the monarch is only 1.17 for the entire set of loci. This does not diminish the evolutionary importance of such a relationship, but rather places realistic expectations on the magnitude of the effect. Furthermore, because we are comparing variances, the ability to make strong statistical inferences about such associations will be constrained without large sample sizes and many independent observations.

The statistical power for the variability measures and sample sizes reported by Handford² is difficult to quantify. Regardless of the drawbacks of the F -test, it can be used in a simple univariate case to illustrate the limitations of these sample sizes. For a normally distributed character, the homozygote/heterozygote F ratios associated with Handford's larger sample sizes which would be statistically significant ($P < 0.05$) are 1.8 (d.f. = 130, 22) and 1.5 (d.f. = 76, 49). These are unrealistically large ratios given the subtlety of the relationship expected and observed in other organisms. The problem of type II error does not disappear by using Handford's particular treatment or by applying the sign test. In addition, Handford uses multivariate measures of variability which further reduces the statistical power with the inclusion of each new character. Indeed, three of the five tests for matrix homogeneity in females cannot be carried out because the sample sizes are so small that there are insufficient degrees of freedom.

His cautionary statement that one nonsignificant result does not negate the relationship is true, but a nonsignificant result for a truly powerful data set would have permitted some strong inference to

be made. Obviously, the need is not for many more tests of weak statistical power, but rather for a few tests, each with sufficient power to distinguish between no relationship and one of small, yet realistic, effect.

WALTER F. EANES

2. Eanes, W. F. *Nature* **276**, 263–264 (1978).
3. Mitton, J. B. *Nature* **273**, 661–662 (1978).

HANDFORD REPLIES—Of course, I agree with what I take to be Eanes' main point: that many more data are needed to clarify the relationship between heterozygosity and morphological variability. Indeed, my modest contribution¹ closed with an implied request that workers (and there must be many) in possession of data sets containing the necessary information (for many taxa and based on larger samples) do the necessary sums and communicate their results. In that note¹ I also made the obvious point that lack of a significant result does not demonstrate much on its own (even though nonsignificance is also evident from the sign test² used by Mitton³ in the interpretation of his results).

Regarding statistical considerations, Eanes is correct about necessary magnitudes of effects when using the *F* ratio. Comment has been made about the use of *F* ratios¹, and will not be repeated. However, I may compare my data with those of Mitton³. If his three localities are considered separately, his samples are comparable, both biologically and numerically, with mine¹. In all three samples, Mitton's data yield a result which is significant by the sign test; mine do not. The sign test is, of course, independent of the magnitude of the differences in variance and of the size of the sample used in computing the variances. Given that there are some *a priori* reasons for expecting that heterozygosity may be of different biological significance among homoiotherms and poikilotherms¹, I felt my results worth communicating.

Nigral-derived muscimol circling—ipsiversive, contraversive or controversial?

REAVILL *ET AL.*'S¹ attempted reconciliation of the dispute between Waddington² and Martin and Haubrich³ raises some important issues. Briefly, the controversy centres on whether disinhibition of dopamine (DA) neurones in the substantia nigra zona compacta (SNC) contributes to the contraversive circling produced by injecting a γ -aminobutyric acid (GABA) agonist into one nigra, as this has been variously reported as being unaffected^{4–6}, attenuated^{7–11} or even exaggerated¹² by measures which reduce nigrostriatal dopaminergic activity. We, too, firmly believe that the precise location of injection of the drug within the nigra holds the key to these disparities. Thus when muscimol (40 ng) is microinjected discretely (in 0.2 μ l over 3 min) into the central region of the zonal reticulata (SNR) at all rostrocaudal levels, it evokes rapid contraversive circling which is significantly (though never completely) inhibited by pretreating the animals with haloperidol (0.1 mg per kg) or pimozide (0.25 mg per kg), intraperitoneally, or 6-hydroxydopamine (4 μ g into the SNC or medial forebrain bundle). That is, it is partially DA dependent (see refs 7–11). On the other hand, injecting the agonist into ventral or lateral aspects of the SNR, irrespective of rostrocaudal coordinates, again stimulates rats to move in contralateral circles, but in this case the rate of rotation is regularly slower and is unaffected by the above treatments. In other words it is DA independent (see refs 4–6). Consequently we believe it is the disposition of muscimol in a mediolateral or dorsoventral direction within the reticulata, and not along the rostrocaudal plane of the nigra as a whole as Reavill *et al.*¹ surmised, that determines whether the resultant circling behaviour involves dopaminergic activation.

The latter could occur by muscimol suppressing the activity of inhibitory interneurons, or of nigrothalamic fibres that send collaterals to the SNR. Our suggestions are in keeping with the known topography¹³ and electrophysiology¹⁴ of this area of the nigra. The assertion that Martin and Haubrich could only have achieved striatal DA release and contraversive circling with muscimol from the caudal nigra is therefore unfounded. Furthermore, our arbitrary division of the SNR into two longitudinal bands from which different types of contraversive circling may be elicited should not be confused with the separate, weaker depressant action of muscimol on the compacta DA neurones directly¹⁴. This will give rise to ipsiversive asymmetry that is totally abolished by neuroleptics⁵. We would agree that this type of ipsiversive

behaviour is most readily evoked from the rostral SNC. In fact, we have never observed ipsilaterally directed movements with muscimol from the caudal SNC. Thus a behavioural distinction can be made between GABAergic drugs acting on the SNC (rostrally) or the SNR (caudally), but this does not account for the above-mentioned discrepancies¹.

To dismiss as 'redundant' the significance of striatal DA release in the mechanism of nigral GABA-mediated circling could be premature, as this presupposes that all such behavioural influences are necessarily channelled back through the SNR, which has yet to be ascertained. This might be true for rotational behaviour generated artificially from the SNR by an agonist as powerful as muscimol, even in 'thalamic' rats¹⁵, but we cannot help wondering if animals bearing chronic cerebral damage can validly be used to predict the importance of events that take place in the whole animal. The elegant experiments of Grace and Bunney¹⁴ favour the opposite view by showing that the firing rates of compacta DA cells are reciprocally related to the activity of non-dopaminergic GABA-receptive cells in the neighbouring SNR. The focal ejections of GABA which raised DA cell firing severalfold were made into the central region of the SNR, the area most densely innervated by striatonigral GABA terminals¹⁶. Cells here are exquisitely sensitive to iontophoretic GABA and it is from this region that we obtained contraversive turning to muscimol which was strongly dependent on dopaminergic mechanisms. There is every reason to suppose, therefore, that these GABA-DA interactions are far from inconsequential in normal physiological conditions.

BOOK REVIEWS

Oil in the wheels of politics

Ian Smart

THOSE who have to catalogue or identify books would sometimes welcome a little more care in choosing titles. Certainly, no one should reach for this stimulating but strangely uncertain symposium in the belief that it will offer a synoptic view of the relationship between energy and security. On the supply side, coal, gas, nuclear power and "renewables" are mentioned in passing, but the emphasis is otherwise exclusively on oil. On the demand side, changes in oil and total energy consumption are duly noted, but the structure and evolution of conversion and end-use patterns are largely ignored. So are all questions of energy technology. As to security, it is understandable that most of the discussions and policy recommendations relate to the United States, albeit against the background of praiseworthy insistence that American isolation from world energy concerns is impossible. What is less acceptable is the absence of any serious reflection on what "security" really means in the energy context. Some of the groundwork is here, for instance in the occasional distinction between import dependence and supply vulnerability. In the end, however, the only definition of energy security, implicitly or by exclusion, is in the all too familiar form of immunity to a sudden disruption of flows or prices in the world oil market. The result is a book about short-term threats to oil trade, with particular reference to the United States. That is undeniably an important subject, but only a broader analysis could hope to determine its true significance.

Any volume made up of separate papers derived from a series of seminars and written by both senior luminaries and graduate students confronts its editors with problems of coherence and consistency. This is no exception. In minor matters — mis-spellings or misprints — the standard is sometimes deplorable. In more important respects, however, there is better evidence than usual of thematic continuity. Nor are the more junior contributors disgraced. Indeed, Fen Hampson on Canadian energy policy and, outstandingly, Kevin Middlebrook on US-Mexican energy relations make two of the most useful and polished contributions to the collection. Some of the problems nevertheless prove insuperable. It has to be said, for example,

Energy and Security. Edited by David A. Deese and Joseph S. Nye. Pp.489. ISBN 0-88410-640-3/0-6660-684-5. (Ballinger/Harper & Row: 1981.) \$14.50, £9.50.

that a book so narrowly focused on oil politics deserves a less superficial survey of politics in the Gulf: a chapter which might, moreover, have carried more weight if, like other sections, it had been reviewed since the outbreak of the Iraq-Iran war. In general, however, the quality of the individual contributions is sufficient, and sometimes exemplary. The intractable difficulty is rather one of reconciling what is said or, more often, implied in the different papers.

In some cases, the impression created is that apparent conflicts of interpretation have been recognized but have resisted resolution. In their summing-up of lessons for American policy, for instance, the editors (with Alvin Alm) strongly endorse the establishment and use of national oil stockpiles, but without referring to some hard questions about that policy raised earlier by Thomas Neff, in a strong paper on recent changes in the oil market. In other cases, the impression is that the participants have simply not addressed themselves to fundamental questions begged by the conjunction of their separate analyses. Two such questions stand out. One is about the relationship between governments and energy markets. And the other is about the relationship between immediate protection against oil-trade disruptions and the ultimate security of energy systems at large.

The contributors are especially uncertain about the role of government. In his opening chapter, Joseph Nye argues for more government involvement in external energy affairs, but less in domestic ones. Other authors echo that view, extolling the usefulness of market forces and casting sceptical glances at the ability of government to regulate or *a fortiori* to ration the flow of oil in an emergency, or even to shape the domestic energy economy in the longer term. Yet, time and again, recommendations for policy action — on stockpiling, pricing, taxation, revenue distribution or the promotion of alternative supply — imply a need for more, rather than less, governmental intervention. The domestic market must be

made free, so that it can transmit price signals efficiently to consumers, but the market must be managed, lest the signals it transmits, as in either the easy days of 1975-1978 or the panic of 1978-1979, reflect an inefficiently short perspective. (David Deese and Linda Miller, in discussing the West European dimension, even complicate the issue by suggesting that, in an emergency, available oil will gravitate towards "free market countries".) Nowhere is there convincing evidence that the contributors and editors have faced up to the obvious dilemma lurking in those shadows. The suspicion they leave is of having convinced themselves that government, in the abstract, must play a role of which American governments, in the real world, are incapable.

The second fundamental but unresolved issue is even more obvious. Several of the authors, led by William Hogan, apparently believe that short-term measures to prepare for disruptions of oil trade have been neglected in favour of efforts to limit oil imports or oil consumption in the longer term. In the particular case of the United States, given the fiasco of the Strategic Petroleum Reserve, it would be hard not to sympathize with them. What is lacking, however, is a considered sense of the opportunity cost of short-term oil emergency measures in relation to the longer-term management of fuel supply and of the energy economy as a whole. A country's relative security in regard to energy palpably depends on much more, in the final analysis, than the scale and pattern of its oil imports. Far larger social, political and institutional, as well as economic, questions are at stake. In this case, however, they remain unilluminated. Anyone who wants to think more deeply about the problems of coping with another Arab oil embargo or the effects on oil supply of another Middle Eastern war, especially in the United States, should read this book. But oil supply is not the only element in national, let alone global, energy security, and anyone who wants to learn about other elements of that now perennial issue will look here in vain. □

Ian Smart is an independent adviser on international energy affairs.

States of matter inside the planets

W.B. Hubbard

Interiors of the Planets. By A.H. Cook. Pp.348. ISBN 0-521-23214-7. (Cambridge University Press: 1980.) £25, \$59.50.

Interiors of the Planets, a volume in the Cambridge Planetary Science series, is intended as a textbook for advanced students. The book reads rather more like an extended review article than a text, however; yet probably no other approach is possible in this rapidly-developing field.

A number of thorough, up-to-date accounts of important topics are scattered through the book. The initial discussion of the Earth and the derivation of interior models from seismic data and the Adams-Williamson equation is lucid, as is the subsequent coverage of heat sources in the Earth and effects on the temperature gradient. The strongest parts of the book are those which deal with measurement of gravitational field parameters and with solid-body planetary motions — the use of artificial satellites, fly-bys and laser retro-reflectors to determine gravitational field parameters and precession and libration constants is considered in some detail; and the first-order theory of figures, leading to the important Radau-Darwin approximation, is given in enough detail to make clear its physical significance.

There are two chapters on equations of state — separated by chapters on the Moon and terrestrial planets — a division which seems a little curious, since similar physical principles are involved. Nevertheless, the exposition of experimental techniques for measuring equations of state and phase transitions is a helpful guide to the intricate transformations which can occur in minerals at high pressure. The chapter on metallic and molecular hydrogen, which comes later, is also fairly complete, and gives the reader a good feeling for the convergence of very different methods for deriving pressure-density relations and other important thermodynamic parameters.

The chapter on the Moon is somewhat sketchy. Lunar seismology and the evidence for a lunar core from the moment of inertia are presented in useful detail, but an adequate discussion of important work on electromagnetic sounding of the lunar interior is lacking. The account of the formation of the lunar crust tends to be unclear — and many workers in this field would doubt the assertion that the crust may have accreted separately onto the Moon, from meteorites, after formation of the mantle.

The discussion of Mars, Venus and Mercury is likewise rather uneven. Moments of inertia are dealt with well, and the author succeeds in giving a clear, simple exposition of the relation between the moment of inertia and the relative effects of crust, polymorphic phase transitions

and core. On the other hand, the effects of tidal dissipation are ignored, and the classic work of Goldreich and collaborators on spin-orbit coupling in terrestrial planets is mentioned only obliquely. Although some attention is given to the higher-order gravity fields of the Earth, Moon and Mars, a geoid map of each is needed for clarity; such a map is given for the Moon only, but without definition of units.

Similarly, the chapter on the Jovian planets has some fairly major gaps. Most discussions of the composition of this group start with the mass-radius diagram for self-gravitating spheres at zero temperature. The existence of a pronounced maximum radius for any such object at about the Jovian radius is convincing evidence for the preponderance of hydrogen in Jupiter and Saturn. Without such a diagram, the reader must take this important result on trust. In

addition, the discussion of the heat balance of Jupiter and Saturn is misleading, and it is quite impossible for the solar wind or ultraviolet radiation to contribute in a significant way to the observed imbalance.

The author makes it clear that *Interiors of the Planets* is not a cosmogonically oriented book. His general theme is the use of established physical principles to draw general conclusions about the present interior state of planets. A synthesis of the derived interior structures of planets does require cosmogonical considerations, but we do not yet know enough to carry out such a synthesis.

The book will not suffice as a sole reference to planetary interiors for an interested student, but it will be a helpful addition to his library. □

Logic in Galilean scholarship

A. Rupert Hall

Galileo and the Art of Reasoning: Rhetorical Foundations of Logic and Scientific Method. By Maurice A. Finocchiaro. Pp.478. Hbk ISBN 90-227-1094-5; pbk ISBN 90-227-1095-3. (Reidel: 1980.) Hbk Dfl.80, \$42; pbk Dfl.40, \$21.

THIS is, as befits the series in which it is published, very much a book by a philosopher for philosophers, a book about logic rather than about Galileo. A scientist, a historian or a general reader wishing to make an initial exploration of Galileo's style as a writer and a natural philosopher would do much better to sit down with an English version of Galileo's *Dialogues on the Two Chief Systems of the World* than to read this volume. Indeed, Professor Finocchiaro's study would be impossibly hard to follow for anyone who has neither familiarity with Galileo's book, to which it is directed, nor with contemporary scholarship in history and philosophy of science.

This is, in brief, a work of detailed and technical criticism, mostly of the logical structure of arguments offered either by Galileo himself or by would-be interpreters of Galileo, both historians and philosophers (and at least one great scientist — Einstein). Finocchiaro exercises singular skill and acuity in the close analysis of reasoning in order to test whether opinions and generalizations purportedly justified by it are valid or otherwise: most commonly he finds them otherwise. Thus he finds grounds for strong reservations about statements or views relating to

Galileo put forward by Alexandre Koyré, Paul Feyerabend, Maurice Clavelin, Dudley Shapere, William Shea, Stillman Drake and many others. To give one example of the elaboration involved: a quotation from a book by Koyré published 42 years ago occupies half a page, its dissection 14½ pages (admittedly of larger print). It is the fine structure of the Koyré passage that is faulted: "it would be unhistorical" the author concludes "to deny that the study of the history of science made great progress with Koyré: to turn the clock backwards is simply unthinkable".

It seems that his object is to make philosophical judgements upon the philosophical positions adopted by other writers on Galileo: Koyré's error lay in his being an apriorist rationalist; Feyerabend's in denying the rationality of Galileo's and modern science; Drake's in being an empiricist or perhaps totally aphilo-sophical, and so forth. This makes the road to a positive understanding of Galileo's reasoning long and hard. On the other hand, Finocchiaro does express plainly his sense of the merits of previous scholars, even though (in his view) all have made serious mistakes, and he has studied the *Dialogue* and the difficulty of translating it with exemplary care, providing very full analyses of both the content and the nature of the arguments used by Galileo.

There are, to me, paradoxes in Finocchiaro's book apart from the paradoxes of Feyerabend, the Zeno of out time. Why does he object to Koyré's writing that the *Dialogue* is "not a book of astronomy, nor even of physics. It is above

all a book of criticism, a work of polemic and struggle; it is at the same time a pedagogical work, and a philosophical work. . . . Why does he write of Galileo's allegedly "Platonic" hypothesis of the planets all being accelerated into their orbits by falling from a unique point in space that "the correspondence is amazingly close"? (It is not, as Newton pointed out long ago in his second letter to Richard Bentley, though Galileo seems to accept it as true.) Why is it profitable or illuminating to treat Galileo's *Dialogue* in case-study fashion as though it were a statement of contemporary science?

Mary Evans Picture Library

It is fair to end with some (abbreviated) conclusions of the author's own:

The evidence from Galileo indicates that science is primarily a method rather than a set of abstract truths; that method involves not the fixed adherence to some formal universal rules, but rather the judicious balancing of such opposites as speculation and observation, quantitative analysis and qualitative considerations. . . ; that in particular such judgment does not automatically exclude rhetorical persuasion or aesthetically expressed emotion; but that such exercise of judgment reduces ultimately to a matter of reasoning, namely the drawing of conclusions from premises and the formulation of reasons for claims.

Finocchiaro ends with the admonition that "in order to become more scientific, the study of reasoning needs a greater empirical orientation towards reasoning as it actually occurs in the world" to be found by employing a "broadly conceived historical approach" not shying away from "attempts at concrete theoretical systematizations". □

Essential techniques in diazotrophy

John Postgate

Methods for Evaluating Biological Nitrogen Fixation. Edited by F.J. Bergersen. Pp.702. ISBN 0-471-27759-2. (Wiley: 1980.) £38, \$114.

To do justice to a book as important as this in a short review is a frustrating task. It is a compendium of modern methods of studying diazotrophy and, as most readers will know, it is largely new (or improved) techniques which have permitted the spectacular advances of the past few decades.

First, a brief survey of its authors and scope. Dalton describes techniques for the culture of nitrogen-fixing bacteria; Bergersen discusses direct nitrogen analyses (for example Kjeldahl, $^{15}\text{N}_2$); Turner and Gibson deal with indirect assays of diazotrophy (acetylene reduction, hydrogen evolution); Gibson copes alone with methods for handling legumes in a laboratory or glasshouse; Bond and Wheeler give details for examining actinorhizal symbioses.

More biochemically, Eady comprehensively surveys methods of extracting, purifying and studying nitrogenase; Appleby and Bergersen deal with leghaemoglobins; Farnden and Robertson attempt, with considerable success, the almost impossible task of deciding what enzymes are metabolically related to nitrogenase, and tell how to handle them — they give priority to plant enzymes. Schwinghamer and Dudman then make a somewhat discursive job of "methods for identifying strains of diazotroph", straying rather often from true practicality and regrettably concerning themselves almost exclusively with rhizobia. In contrast, Cannon's terse chapter on everything you need to know to study the genetics of diazotrophs is a masterly laboratory manual in itself.

Brockwell's wide experience informs his chapter on crop and pasture legumes, which takes the reader out into the field; a comparable authority pervades Thompson's chapter on legume inoculants. Dobereiner describes the relatively new if controversial area of diazotrophic associations involving grasses and grain crops — her account of the much-criticized excised root acetylene assay, as well as other techniques, is useful and balanced. Knowles's chapter on plant communities and soils extends coverage to natural ecosystems; finally, Stewart presents a synoptic view of the cyanobacteria and their associates, detailed and down to earth on the free-living types, less practical on the symbioses.

With such broad coverage some defects are inevitable and I must mention a few. Someone ought to have warned about the hazards of "ghosts", those bacteria which scavenge atmospheric fixed N (NH_3 or

NO_x) and so simulate diazotrophs, for they are still responsible for occasional false reports of diazotrophy. Bergersen should have mentioned the use of ammonia electrodes, and also warned researchers not to smoke, sweat or permit reagent ammonia in the room (or work near stables!) when doing Kjeldahl analyses. Thompson ought to have warned of the inherent error of Petroff-Hauser chambers (they overestimate). Indeed, enumeration of diazotrophs can be tricky and it is inadequately discussed. Dobereiner considers the enumeration of some, but the topic ought surely to have been in Dalton's brief. Dalton also omitted the important problem of colonial multimorphism in putatively pure strains of rhizobia: Dr Elkan has shown that they can have different phenotypes and require special detergent media to be seen. Finally, despite its use in California, I question Farnden and Robertson's recommendation of a tritium exchange to assay uptake hydrogenases: tritium uptake is more sensitive and theoretically sounder.

No doubt other criticisms could be made, but they all become trivial in the context of the excellence of the book as a whole. Dr Bergersen is to be congratulated on choosing authors with direct, practical experience of their subjects and ability to communicate that experience to the reader. The information in this book will have a very much longer half-life than that in most of the more theoretical books and the symposia on diazotrophy which are now being published with such regularity. This one is essential for any laboratory teaching or researching in this area and even experienced research workers will benefit from dipping into it. □

John Postgate is Professor of Microbiology at the University of Sussex and Director of the Agricultural Research Council's Unit of Nitrogen Fixation.

T-cell controversies

Werner Haas

Regulatory T Lymphocytes. Edited by Benvenuto Pernis and Henry J. Vogel. Pp.449. ISBN 0-12-551860-9. (Academic: 1980.) \$47.50, £26.50.

THIS collection of papers and review articles about suppressor (T_S) and helper (T_H) T cells was written by a group of experts, mainly from the USA, who met in June 1979 at Columbia University. The majority of findings described are poorly understood and controversial; they will challenge the expert and confuse the non-expert.

Outstanding is the article by Sprent indicating that T_H interact only with B cells and macrophages expressing Ia antigens when encountered by the T cells in early differentiation. Confirmatory and contradictory experiments are discussed by Pierce and Kapp, by Mitchison and by Marrack *et al.* A more detailed analysis of regulatory T cells requires *in vitro* experiments. As yet, informative data are rare, but there are some studies in the right direction — selection in long-term cultures (Augustin *et al.*) and limiting dilution analysis of specific T_H (Zauderer *et al.*), and isolation of a T_S clone (Cantor and Gershon) are discussed here. Current experiments concerned with the serology and biochemistry of antigen-specific T cell receptors and factors are referred to in several articles and some details are described by Cramer and Krawinkel, Goodman *et al.* and Geha. Melchers and McDevitt present a clearly written, comprehensive review on the selective expression of Ia antigens by T cells. Functionally distinct human and murine T cell subsets identified by a variety of antisera and monoclonal antibodies feature in papers by Micklem *et al.*, Friedman *et al.* and Reinherz and Schlossmann; identification of subsets by red cells coated with different classes of antibodies is considered by Fauci and by

Moretta *et al.* An impressive amount of work, presented or reviewed by Fauci *et al.*, Siegal and Siegal, and Waldmann *et al.*, suggests that a variety of human diseases are associated with or caused by various forms of "disordered immunoregulation".

There is general acceptance of Jerne's notion that antigen-specific receptors must be the primary target of any specific regulatory mechanism in the immune system. This experimentally demanding issue is considered in more detail in articles on idiotype-specific T_S by Bona and Paul and T_H by Eichmann and Simon, Ig dependent T_H by Janeway *et al.*, allotype suppression by Tokuhisa *et al.* and T cell mediation of resistance to graft versus host disease by Wilson *et al.* Finally, Herzenberg and colleagues demonstrate how to express complex ideas in clear drawings.

The book will be a disappointment to readers who expect more definitive reports on the various types of T_H and T_S , H-2 restriction of T_S , inducer cells and feedback inhibition, regulation of cytotoxic T cell responses or on the various types of T cell factors inducing lymphocyte proliferation and/or differentiation. □

Werner Haas is at the Basel Institute for Immunology.

after-discharges in the same system. There is, however, a danger in generalizing from epileptics to normals since there must be something abnormal in the epileptic brain to cause the discharge in the first place.

In the absence of interesting new results to report, most of the contributors resort to the banal. It is no surprise that the brain waves produced in transcendental meditation resemble those in sleep or that they cannot be distinguished from those occurring when listening to soft music or during progressive relaxation. Nor is it particularly revealing that Italians asked to endure high levels of shock are sensible enough to call off the experiment sooner than do Yankee Protestants.

Much of the theorizing is at the same level of banality. C. E. Izard cites with approval W. Charlesworth's opinion, doubtless reached after years of wrestling with the problem, that "surprise is a misexpected object or event", whilst Karl Pribram, in one of the few intelligible sentences in his chapter, enlightens the ignorant reader with the news that "Science pursues knowledge by observation and experiment".

Most of the book's theorizing is so nonsensical that it is impossible to describe. Its level may be gauged by the following quotation from the chapter by R. J. Davidson, one of the editors:

The term 'unconscious' is here being used . . . (1) to refer to mental structures . . . which contour and transform both exogenous (from the environment) as well as endogenous (from within the person . . .) information, and (2) to refer to processing activity, action and/or information transmission in the nervous system which proceeds in the absence of conscious awareness . . . The first usage makes reference to internal mental (i.e. biocognitive) structures . . . The second usage is concerned with observable behaviour (either directly or indirectly) of which the subject is unaware.

One cannot evaluate Dr Davidson's claim to have uncovered two kinds of unconscious process, since he is clearly unable to put the difference into words: nor does he explain what is meant by "observable behaviour of which the subject is unaware". In an equally silly chapter, Pribram argues that "feedforward" operations require consciousness: the reader who wants to know what feedforward is learns that it is "feedbacks joined into parallel processes".

Much of the book — and all of its theoretical sections — is a farrago of pretentious rubbish; it is atrociously written, with the usual attempt to make commonplace ideas sound important by the introduction of neologisms. In short, the book is a disgrace to the publishers, the editors and the contributors. □

Stuart Sutherland is Director of the Centre for Research on Perception and Cognition at the University of Sussex.

Unconscious pretension in psychology

Stuart Sutherland

The Psychobiology of Consciousness. Edited by Julian M. Davidson and Richard J. Davidson. Pp.489. ISBN 0-306-40138-X. (Plenum: 1980.) \$32.50, £20.48.

ONE of the most significant changes in psychology over the past two decades is that consciousness has become respectable. Several separate developments have brought it back to fashion, including the realization that behaviourism can offer no explanation for many actions, the development of computer simulation as a method for modelling complex thought processes, the increasing interest in Western society in attaining "altered states of consciousness" either through psychotropic drugs or by meditative practices, and the discovery of many different transmitter substances that are involved in the regulation of mood. It is with the latter two themes that *The Psychobiology of Consciousness* is mainly concerned.

The field appears to be in such chaos that the attempt to think about it has reduced the book's 15 contributors to incoherence. Their strenuous efforts to resuscitate the shade of Titchener by recording and classifying states of consciousness, both normal and abnormal, have met with no success. The few interesting new findings

they present have little unity. Typical examples of such isolated discoveries are that since large quantities of marijuana usually have little effect on novices, new users of the drug have to learn how to become "stoned", and that there is a tendency to look to the right (which may mean that the left hemisphere is being used) when thinking verbally, and to the left when working out spatial problems.

Perhaps of more significance are some recent studies of temporal lobe epilepsy. Synchronous spiking of nerve firing within the temporal lobe can be accompanied by feelings of ecstasy, religious awe and extreme kindness, and it is usually associated both with a lack of interest in sex and with the absence of any form of addiction. Treatment of the spike focus to eliminate the hypersynchrony often alters the epileptic's personality for the worse. His irritability increases, and he may become unhappy: he regains an interest in sex, but usually loses his religious preoccupations. Although A.J. Mandel does not go so far as to allege that St Paul had a seizure on the road to Damascus, he does argue that ecstasy is normally accompanied by hypersynchronous discharge in the limbic system excluding the amygdala and that the prolonged state of saintly kindliness that ensues depends upon

23 April 1981

Tenth birthday for the environment

1982 will be a red-letter year in the history of the United Nations Environmental Programme, for then the newest of the United Nations agencies is planning to celebrate the tenth anniversary of its foundation, at the United Nations Conference on the Environment in Stockholm. The meeting of the agency's governing council planned to open on 13 May in Nairobi will be asked formally to approve the plans that have been laid to celebrate the occasion. There is, for example, to be a "session of a special character", a week-long occasion for mutual congratulation and exhortation, sandwiched into the normal proceedings in 1982. For this jamboree, nations which are not members of UNEP itself will be invited to attend, the only necessary qualification is that they should be members of some other United Nations agency or of the International Atomic Energy Agency. Those arriving in Nairobi in 1982 will be provided with a "60-70 page report" by the executive director, dealing with past and future environmental challenges, together with the annual document in which the agency spells out its estimate of the then "state of the environment". The meeting of the governing council next month will be asked to approve an outline of these documents and also a budget for the "session of a special character" which amounts to \$442,000, including \$163,000 by way of fees to the consultants who will be asked to prepare the special documents. It will be interesting to see how many of the delegates in May consider that, at something like \$2,500 a page, the cost may be excessive.

Compared with some other United Nations agencies, UNEP is neither ostentatiously extravagant nor obviously bigger than it needs to be. The agency rubs along on a mere \$5 million a year, spending perhaps twice as much on specific programmes to which member states contribute separately and voluntarily. Plainly it is not living off the hog, while it is not outrageous, at least by the standards set by other international organizations, that it should spend the best part of \$500,000 on a self-congratulatory conference a year from now. The more important question, which the delegates to Nairobi should ask themselves in May, is whether they should not spend their "session of a special character" the following year considering whether their agency is pointed in the right direction.

The most serious danger, clearly apparent in Stockholm in 1972, was that the agency might be allowed to tackle the variety of insoluble problems on which the founding fathers had set their hearts. That, fortunately, has been avoided, chiefly because governments were unwilling to provide the necessary funds. Since then, the agency has made its way in the world with a number of good works of a more unspectacular kind. It has helped to bring the convention on Pollution in the Mediterranean into being — and in the past few weeks has been seeking to do the same for the Caribbean (see p 622). It has competently taken over from the headquarters in New York the management of the United Nations committee on nuclear radiation.

Only in two respects can it be seriously faulted. Over the years, the agency has taken the view that a large part of its objective should be to "raise the consciousness" of member governments on environmental matters, which is entirely proper. But in doing so, the agency has taken to using the rhetoric of the extremists in the environmental movement. A simple booklet, published the other day and consisting of a reprint of the Stockholm Declaration and related documents, is loosely and unnecessarily called "In defence of the Earth". And, in attempting to draw attention to environmental problems, the agency has often fallen

into the trap of dramatizing them. A session of a special character in 1982 might usefully try to bring the agency back to earth in these respects. At the same time, UNEP could usefully be pointed in the direction of tasks that need to be carried out, and which are squarely within the terms of reference with which it was blessed at Stockholm. All member states, but developing countries in particular, are much in need of some way of ordering priorities in the commitment of resources to the improvement of the environment. UNEP could usefully shoulder these simple tasks, and earn itself a reputation in the process.

Going private

Under what circumstances can a research laboratory established under the wing of a protective government be legitimately turned into a private enterprise? Since its election nearly two years ago, the British government has been doing what it can to sell off assets which it has accumulated, sometimes by accident. A large block of shares in British Petroleum, the oil company, has already been disposed of, as well as 49 per cent of the shares in British Aerospace, a conglomerate of miscellaneous manufacturing concerns. In due course, the government also plans to sell off enterprises such as Cable and Wireless, the publicly owned international telecommunications concern. The chief objective of these sales of public assets is to raise cash that can be used to span the annual gap between government expenditure and revenue — and it is an open secret that the government is disappointed that "privatization" (as the jargon has it) has so far accomplished so little. Partly as a consequence, but also because the government is rightly persuaded that the strength of the civil service should be reduced, attention has now turned to the conversion of public laboratories into private enterprises of various kinds. The immediate danger is that the government may not be able to distinguish between the shedding of a laboratory and the shedding to the stock market of the public interest in a block of shares in some enterprise whose management is otherwise unchanged.

Several public laboratories are in various stages of being turned out into the private sector. The simplest case is that of the Radiochemical Centre at Amersham in Buckinghamshire, which supplies radioactive isotopes and chemicals containing them to an impressive array of customers throughout the world. Technically, the centre is constituted as a limited company, the shares in which are held by the UK Atomic Energy Authority, acting as a kind of public trustee. The 1,500 or so employees are not civil servants in the strict sense. The enterprise makes a tidy profit (nearly £1.5 million in 1979-1980), and has a marketable record of growth over the past decade. Although potential purchasers will be disappointed that the profit is merely 3.5 per cent of the turnover, there is every chance that this sound business could be sold as a going concern without interfering in the short run with the management of the laboratory. The government's chief concern, when it invites tenders for the centre a year or so from now, is likely simply to be that the Radiochemical Centre is not snapped up by some unwelcome bidder. Privatization will be found to have been painless.

The other laboratories on whose disposal the government has set its heart will not be as simply turned out into the cold. The chief of them is the Hydraulics Research Station, which has over several

years acquired an enviable reputation for model studies of hydraulic projects, many of them overseas (see *Nature* 9 April, p 438). Over the years, successive governments have expected different things of the laboratory. Sometimes the laboratory has acted as a hidden subsidy of the export trade. Now, with the doctrine that those who call the tune should pay the piper sweeping through Whitehall, it is natural enough that this laboratory should find itself one of the first on the edge of unfamiliar and apparently hostile territory. The laboratory will not, however, be the last to find itself in this position.

The most serious doubt about the government's intentions concerns the prospectus which the staff at the laboratory is being offered. The assumption seems to be that if the laboratory were established as a private company, it would be able to make its way in the world by selling its services to those who use them now. The most obvious difficulty is that the fees which have been charged to, say, construction companies looking for technical appraisals of proposed designs have not fully covered the overhead cost, and especially the cost of long-term research. Those working at the laboratory, and the Institute of Professional Civil Servants which represents the scientists among them, are naturally acutely aware of the risks they are being asked to run. The government seems so far to have failed to still their recalcitrance.

The underlying difficulty is that there is a genuine conflict of interest between the government and the staff at the laboratory. The government, in its role as employer, most probably adequately represents the national interest in holding that applied research laboratories providing a service for customers need not be a part of the public service. But those who work in these laboratories and who have become accustomed to the apparent but often illusory benefits of being civil servants cannot be expected spontaneously to subordinate their personal interests to the greater good. The most immediate fear, at the Hydraulics Research Station but also in other laboratories where privatization threatens, is that the private enterprise will not need, or will not be able to afford, all the staff now working for them. Another problem is that public servants, unlike employees in private concerns, know in advance what their financial prospects are. The government cannot hope without trouble to spin off this or any other laboratory without compensating those directly concerned for the risks they are expected to run. There should be a generous promise of support, over a period of some years, for the core of basic research essential to commercial success. To meet the proper fear of redundancy, the government should undertake that members of staff at the laboratory will not in, say, the next seven years be worse off than if they had remained in the public service. And, to sweeten the pill, arrangements should be made that, in the immediate future, members of the staff should actually be a little better off. For if the objective is to wean public servants to life in the commercial world, is it not in everybody's interest that they should be helped to appreciate the benefits of an equitable bargain?

Supersonic scandal

Ironically, the successful landing of the United States shuttle in the Mojave Desert last week coincided with the publication in Britain of a powerful economic case against the supersonic Concorde aircraft. At this stage, the shuttle is far from being an economic proposition. The cost of development (nearly \$10,000 million) is already substantial, it is unlikely that the National Aeronautics and Space Administration will seek to recover any substantial part of this in the charges made to the ultimate users of the spacecraft and, of course, unforeseen snags may add still further to the cost of the whole development programme. But the shuttle has promise, and probably a future. Concorde, by contrast, is a technological project with a past but no future. The House of Commons Industry and Trade Committee last week published figures showing that Concorde is at present uneconomic and likely to become even more of a drain on the

financial resources of its operator, British Airways, as fuel costs increase. When the British government is skimping on public expenditure in all its works, Concorde's capacity to keep flying must be an open and urgent question.

Since its inception in 1962, the Concorde project has been an assault on economic reality. The then Mr Peter Thorneycroft (now Lord Thorneycroft and chairman of the British Conservative Party), as a member of a British government seeking entry to the European Community, seems to have persuaded himself that an Anglo-French collaboration on the development of a supersonic aircraft would have political advantages outweighing the economic costs of the enterprise. In the event, Concorde did not overcome General de Gaulle's objections to British membership, but it was left to a later British government to discover that the Anglo-French agreement about Concorde was legally indissoluble. Technically, the promise of the aircraft was always limited. Concorde was conceived of as a first modest venture into the supersonic regime for a passenger aircraft. As an economic proposition, it was too small and too slow. Optimists, two decades ago, brushed aside these faults by saying that the first Concorde would quickly be followed by other economic aircraft. In the event, there have been no successors — or even serious suggestions that there should be. The British and French governments have between them spent £1,200 million on the development of this first aircraft, and yet must continue to subsidize their nationalized airlines to keep Concorde in the air.

The cost of keeping the aircraft in the air is still substantial. Both airlines have been forgiven the cost of developing the aircraft, and British Airways has also been forgiven the £160 million cost of buying six aircraft (one of which is now out of service). Yet even though the cost of a seat on Concorde is 20 per cent more than the cost of a first-class fare on a conventional aircraft travelling the same route, British Airways is able to come within sight of breaking even only on the route between London and New York. On the whole of its Concorde operations, the airline reckons that it will have to spend £65 million more than it earns from them in the next five years. The airline told the committee that some advantages accrue to it from being seen to have a continuing interest in supersonic flight, a calculation of the intangible that does not apparently prevent British Airways asking the British government for an annual subsidy for its Concorde operations. The committee concludes that the case for Concorde is so shaky that there should be commissioned an independent financial investigation of the continued operation of the aircraft. The surprise is merely that the committee did not recommend, on the evidence that it had gathered, that the airline should turn its back on Concorde before more money has been wasted on the enterprise. Why should taxpayers, or other airline users, continue to subsidize an enterprise without financial or technological promise?

The issue is deeper than that of how a nationalized airline manages its internal affairs. To the extent that supersonic aircraft, Concorde in particular, have become identified in the public mind with the process of innovation, the continued operation of a tiny fleet of loss-making aircraft can only injure the reputation of technology as a whole. The figures assembled by the Commons committee show that the average cost of carrying a passenger from London to New York by Concorde (£543) is more than three times the corresponding cost by conventional wide-bodied aircraft. Although a substantial part of the extra cost is that of fuel — in a sense, bad luck — the poor utilization of the aircraft (on average, 2.6 hours a day) and the high cost of persuading people to buy tickets on the machine also help to make Concorde operate in the red. These extra costs will hang like an albatross around the neck of British Airways for as long as it persists in flying an uneconomic supersonic aircraft across the Atlantic. For as long, British taxpayers will be asking what the British government can intend by exhorting everybody in sight to productive industrial innovation when it chooses to spend part of its income from taxation on an unproductive innovation such as Concorde. The enterprise, wrongly conceived twenty years ago, should now be brought speedily to an end.

Telecommunications monopoly eroded?

Profiting from leased lines made seemly

The most serious challenge yet to the British telecommunications monopoly came last week in a recipe for permitting outside access to the public network. A report by Professor Michael Beesley, *Liberalization of the use of British Telecommunications Network*, commissioned by the Department of Industry, argues that private persons and companies should in future be allowed to set up separate networks but also to market telecommunications services based on circuits rented from British Telecom.

In passing, the report provides a unique account of competition between telephone monopolies and those who use their circuits for marketing private services, notably in the United States. Thus MCI Inc., one of the survivors of the companies set up in the 1960s to provide data transmission services using lines leased from AT&T (the telephone company), told Beesley that 91 per cent of its business now stems from voice and not digital transmission.

In principle, the Beesley report is intended to allow the British government to fill in some gaps in the Telecommunications Bill, still being discussed in the House of Commons. When the bill was published last October, the Department of Industry promised that provision would be made for private interests to lease lines from British Telecom, reselling the services thus made possible. In practice, opposition from British Telecom — and the sheer unfamiliarity of the Beesley proposals on the British scene — may postpone these developments.

Jargon for these services is VANS, or "value added network services". Beesley concludes that in the domestic British market there should be no restriction on the use made of British Telecom circuits by those who rent them. British Telecom, the report says, should be required to publish the costs of renting circuits of different kinds, and the charges made should be unrelated to the proposed uses. (British Telecom's proposal that it should charge royalties on VANS is rejected.) British Telecom itself should be free to compete in fields such as data transmission. Ultimately, Beesley argues, liberalization of the monopoly should be extended to the international market.

The crux of the report is Beesley's rejection of the British Telecom protest that liberalization would allow private users to "skim the cream" off its

telecommunications market. British Telecom itself has estimated that unrestricted use of its domestic circuits would lead to revenue losses of between £30 million and £110 million, and that one consequence would be slower development of the telecommunications network in Britain. Beesley doubts the arithmetic (which implies a faster growth of VANS services in Britain than in the United States), says that the public monopoly could safeguard its position by adjusting tariffs more accurately to costs and argues that the partitioning of the telecommunications market is not, in any case, a "zero-sum game". The sale of VANS would increase the amount of business to be shared by British Telecom and those selling services based on leased circuits.

As yet, Beesley finds, there is no clear pattern of how British private users would exploit the freedom to use British Telecom circuits. The most obvious starting point would be the provision of long-distance telephone services, perhaps of lesser quality, more cheaply than British Telecom. But several organizations with existing private networks — one of them the nationalized industry British Rail — have ambitions to make more use of their existing telecommunications networks.

Although the Department of Industry, the department responsible for telecommunications, favours the principles underlying Beesley, the process of consultation is expected to take several months. Political and trade union opposition is likely to be fierce.

Postgraduate medical schools in danger

The University of London's postgraduate medical schools may be the first British academic institutions to bite the dust in the wake of government cutbacks in funds for higher education. A meeting between their representatives, Lord Annan (the vice-chancellor), the Secretary of State for Education and Science and the Health Minister, before Easter, did not secure more cash but did, apparently, convince the government of a problem that it had not known existed.

At risk are the 13 members of the British Postgraduate Medical Federation and two unassociated schools, the Royal Postgraduate Medical School and the London School of Hygiene and Tropical Medicine. Their problems began last October, when government support for new overseas students was cut. The decision that such students should pay "economic" fees has since been exacerbated by reductions of central funds for universities.

The members of the British federation, with 44 per cent of their students coming from overseas, decided to charge the minimum recommended fee of £5,000 even though their average costs are considerably more. A further problem is that a fair proportion of their students are salaried staff whose fees are waived, for which the schools now receive no offsetting compensation. The result is a substantial deficit which this academic year the federation may just be able to balance with help from central funds.

The fear now is that matters will get worse. The intake of overseas students is expected to fall considerably next October. Already several governments, in particular those of Malaysia and Hong Kong which traditionally send many medically qualified students to study in Britain, have said that in future they will be sending students to cheaper universities in other countries. If the expected shortfall

materializes, some of the federation's institutes may find themselves almost bankrupt by the end of the 1981–82 academic year.

That, according to Mr D. Innes Williams of the British federation, would have "disastrous consequences" for teaching and for London's health services. Most teaching and research would have to stop and the clinical staff would be absorbed into hospitals. One possibility, that could keep the institutes functioning although crippled, would be that the government should make up the costs after fees from overseas students have been deducted.

Another possibility, is that some of the smaller institutes could become departments of the major teaching hospitals. Discussions to incorporate the Institute of Dermatology into St Thomas's Hospital are already under way. The larger institutes, however, are hoping to manage on their own.

Although there are many similarities, each institute seems to have its own peculiar problems. The Institute of Basic Medical Sciences, for example, is considering merging with the Royal College of Surgeons, which would have to put up considerable funds to bail it out of its present difficulties.

The Institute of Cancer Research, which is affiliated to the university but receives no funds from it, is suffering not so much from the shortfall in overseas students as from a decision taken in 1977 by the Medical Research Council and the Cancer Research Campaign, which provide it with the bulk of its funds, to reduce their block grant. The institute is now in the position of having spent most of its reserves to make up the deficit and of having its block grant cut even further a year from now. Plans are already under way to persuade staff to retire early. Teaching may be cut in order to retain an adequate research base.

Judy Redfearn

Environmental asbestos

Dispute on levels

Brussels

The European Commission's proposed directives on asbestos have come under attack from all sides. Many of the criticisms put forward by the European Parliament and environmental groups relate to the tougher restrictions on crocidolite (blue asbestos) than those for chrysolite (white asbestos). The dispute highlights the present uncertainty as to what can be considered a "safe" exposure to asbestos fibres.

Following the adoption of a framework directive on asbestos in 1976, the Commission has been working on four implementing directives. Two have already been put forward: one on the marketing and use of certain dangerous substances and preparations; and the other dealing with the protection of workers from occupational exposure to asbestos.

The draft directive on marketing would ban crocidolite except in the manufacture of asbestos cement pipes, acid-resisting seals, gaskets and gland packings. The marketing and use of chrysolite and other asbestos fibres would be banned for thermal and acoustic insulation, air filtering and roadway surfacing unless "the harmful use of fibres is prevented".

The directive on occupational exposure has provoked the greatest discussion. This sets limits on the concentration of asbestos fibres in the air, together with a ban on asbestos spraying, access restrictions, the keeping of health records and a commitment to introducing suitable substitutes as soon as these are available.

The Commission's proposal assumes that crocidolite is five times more dangerous than other types of asbestos. The maximum concentration allowable for crocidolite is 0.2 fibres per millilitre of air, compared with 1 fibre per millilitre for all other types.

Evidence presented at a recent international symposium on the biological effects of mineral fibres supports the Commission's position. Although earlier research with animals had shown that fibres of the same length and diameter cause the same number of mesotheliomas in the lung, more recent research suggests that human lungs react differently to different types of asbestos. Chrysolite enters the human lung less easily than crocidolite and clears more rapidly.

Some members of the European Parliament's Environment and Public Health Committee feel the evidence is inconclusive, and others feel it is confusing to have two different limit values. The Commission thinks that if a single limit value were to be adopted, it should be at the lower level of 0.2 fibres until further research is carried out. But other committee members favour using the upper level of 1.0 fibres. **Jasper Becker**

Spinning off research

Further reductions in the scale of in-house research carried out within the British Department of Defence are promised in the annual "Statement of the Defence Estimates", published last week. In a brief section on research, the white paper says that, in the years ahead, further efforts will be made to place design and development contracts with industrial companies.

This policy, recommended in a study begun in 1979 under Lord Strathcona, Minister of State at the Department of Defence, also recommended that private industry should be given (on a contract basis) more responsibility for the provision of technical and other services to the British defence research establishments. The white paper records with pride a 15 per cent reduction of research manpower between 1974 and 1980, one third of this in the last two years of the period.

At the same time, the ministry is planning to switch resources within its research establishments to long-range studies of various kinds. It cites as one promising field of research a programme now under way to develop an anti-tank weapon in which a single projectile will release a clutch of separate missiles independently guided (with the help of microprocessors) towards separate tanks.

Space shuttle

Bonding problems

Washington

As the US space shuttle achieved its first orbital test flight last week, the National Aeronautics and Space Administration (NASA) was working on proposals for an alternative thermal protection system involving large carbon/carbon panels rather than the ceramic tiles used so far.

The tiling system has been the Achilles' heel of the whole shuttle programme. Difficulty in fixing the tiles securely to the aluminium skin of the orbiter was largely responsible for the two-year delay — and corresponding cost overruns — in the first launch, and the problems are still not solved.

During last week's flight, seventeen of the protective tiles covering the engine housing on the upper surface of the shuttle became partially or totally unstuck during the launch. NASA maintained optimism, saying that none of the more important tiles on the bottom of the shuttle had been damaged, and fortunately this optimism proved justified when the shuttle returned safely to Earth.

The problems that have plagued the development of the present heat protection system — which requires 31,000 tiles, each between six and eight inches square, to cover 70 per cent of the spacecraft's surface — have recently led the space agency to

Shuttle tiles, a sticky problem

look closely at different systems which might be used for future orbiters.

During re-entry, the wing tips and bottom surfaces of the shuttle are required to withstand temperatures of up to 1,370°C. In missiles and other conventional spacecraft, such temperatures have been tolerated by the use of an ablative heat shield which burns away during the heating; but as the space shuttle depends for its cost-effectiveness on reusability, a different solution had to be found.

Using what was the most advanced technology in the early 1970s, the shielding was designed to be provided by tiles of low-density high-purity silica fibre — sometimes referred to as "foamed glass" — made rigid by ceramic bonding. There are about 20,000 of these tiles on the bottom of the Columbia, the average size being about six inches square, and the thickness varying between 0.5 and 3.5 inches.

Each tile is bonded to a pad made of Nomex felt, and the total composite skin can heat up without placing stress on the silica, which is relatively easy to repair.

The ceramic tiles have the disadvantages, however, of being both brittle and not very strong. Furthermore, the aerodynamic stresses on the surface which tend to pull the tiles from the felt which binds them to the shuttle skin had been underestimated — whereas the bonding had originally been required to withstand pressures of up to seven pounds a square inch, in practice the stresses turned out to be twice as high.

The situation became particularly embarrassing when some temporary tiles were lost during the shuttle's transportation flight from California to the launch site in Florida two years ago. And subsequent weaknesses revealed by an intensive programme of "pull-testing" required a lengthy process of densification of many thousand tiles before NASA considered that they were safe.

In the light of these difficulties, NASA last year awarded a contract to Rockwell Corporation Inc. in Downey, California, for a study of alternative thermal protection systems. Three alternative systems

are being studied, each involving a combination of three different forms of protection. For temperatures less than 540°C, insulation would be provided by panels of titanium facing covering an insulating honeycomb. In the 540°C to 980°C range, the same arrangement would be used, this time using a superalloy known as Inconel 617.

The most significant change would be in the high temperature panels, where heat shielding would be achieved by panels of reinforced carbon/carbon, up to three feet square. Various insulating materials would be placed between the shielding and the aluminium surface. The panels would be mechanically attached to the shuttle, avoiding the bonding problem associated with the ceramic tiles. Carbon/carbon is already used in limited quantities for the nose-cap and the leading edges of the shuttle's wings.

But however the new systems perform, there is still the problem of cost to be resolved. Moving to a new system would be expensive, and NASA may not be able to afford a switch.

David Dickson

Nuclear reactor safety

Go for Super-Sara

Brussels

The months of deliberation in Brussels on the future of the Super-Sara project have ended with a decision to press ahead on the lines of the Commission's original proposal. The EEC's joint research centre at Ispra in Italy will now be able to start the second phase with funds totalling 50 million European Units of Account (£0.54 = 1 EUA).

The Super-Sara project will use the experimental ESSOR reactor to study loss of coolant and other accidents in water reactors. More than 200 staff have been left in limbo since last November when the member states first began to hesitate about releasing the bulk of the project's money. In March 1980, 3.31 million EUA was granted for feasibility studies after the project was agreed in principle. But when it came to making available the 40 million EUA for the major part of the project, Germany and others began to have cold feet. The negotiations over the past six months left Germany as the only member state withholding agreement. Germany has now given way to pressure from its partners but has insisted that the project be kept below its budgetary ceiling.

However, the European Commission's initial cost projections have had to be raised since they were first made last year. Automatic salary increases and rising equipment costs mean that 64 million EUA needs to be set aside to take the project up to 1983, when it is due to be reviewed.

It seems increasingly likely that it will overshoot its schedule by as much as two years.

Jasper Becker

Election in Israel

New deal for science?

Rehovot

If, as expected, Labour Party leader Shimon Peres becomes Israel's next Prime Minister after the election in June, he will be the first man with a good grasp of science and technology to hold that office. Although not a scientist or engineer himself, Peres was responsible for initiating many large-scale research and development projects undertaken by the Ministry of Defence, where he served from 1952 to 1977, becoming minister in 1974.

These projects contributed substantially to Israel's military capabilities and also laid the groundwork for its sophisticated aircraft industry (with a turnover in 1980 of \$500 million) and for its rapidly developing electronics industry. Indeed, a very large percentage of Israeli exports based on local research (an estimated \$1,000 million last year) were spin-offs from defence research set in motion by Peres.

Peres, Prime Minister in June?

Peres has placed heavy emphasis on science-related projects in outlining the goals of a Labour-led government. There are plans for a huge "science city" in the Galilee, heavy government subsidies for energy research, a continuation of the recently inaugurated Mediterranean-Dead Sea Canal project for hydrological power and, significantly, the establishment of two nuclear power stations in the Negev.

Israel already has two research reactors, a 5-MW facility supplied by the United States and set up just south of Tel Aviv, and a more controversial 24-MW reactor from France, located near the Negev town of Dimona. But, despite an absolute dependence on imported fossil fuel for the generation of electricity and the existence of the necessary nuclear technology, Israel still has no nuclear power stations.

This anomalous situation arises primarily because the United States, the most obvious supplier of such power stations, is prevented by the Anti-Proliferation Act from selling them until

Kamikaze to Halley

The European Space Agency (ESA) is hoping to enlist the help of the Soviet and Japanese space agencies in sending its Giotto spacecraft on a kamikaze mission to Halley's comet in 1986. ESA would like to send Giotto to within 200 km of the comet's nucleus to observe molecules evaporating from it before they recombine or are interfered with by the solar wind. Initial plans had assumed a closest approach of 1,000 km because of the difficulties of pinpointing the precise position of the comet in advance and because of the risk to the spacecraft of cometary dust. If Giotto gets within 200 km of the comet it may manage a couple of hours of observation before being destroyed.

Such a close approach can only be made, however, with help from the Russian space agency which is also sending a spacecraft to the comet. The hope is that data from the Russian craft, due to arrive at the comet four days before Giotto, could provide precise details of the comet's whereabouts and allow last-minute corrections to Giotto's course. The Russian spacecraft itself will not be able to approach nearer than a few thousand kilometres to the comet nucleus because, unlike Giotto, it lacks a dust shield.

The Japanese space agency will also be sending a spacecraft — at 135 kg the smallest of the three — to photograph the comet in the hydrogen Lyman alpha line. The three space agencies are discussing how they might exchange data gleaned from their separate missions, and next summer the three, together with the US National Aeronautics and Space Administration (NASA), will be meeting to discuss a collaborative project between all four agencies. Although NASA has no mission of its own to Halley's comet, it is organizing a "Halleywatch" which will make use of ground as well as space based observations.

Judy Redfearn

Israel signs the nuclear non-proliferation agreement and opens its nuclear facilities to inspection by the International Atomic Energy Agency.

It was only after Egypt signed this agreement in February that the United States agreed to provide that country with two nuclear power stations with a combined capacity of 2,000 MW. But Peres refuses to say whether a Labour-led government will do what all previous governments have refused to do, namely sign on the dotted line, or, if not, how he expects to get the reactors he proposes to place in the Negev.

Peres sees a close link between the country's economic development on the one hand and its scientific and technological development on the other. He accuses the present Begin government

of allowing the economy to stagnate and, as a result, setting in motion a brain drain that has deprived Israel of thousands of scientists and engineers.

But many specific questions remain unanswered. Will, for instance, Labour create a Science Authority or even a Ministry of Science to take over from the virtually moribund National Council for Research and Development?

Also unclear is the amount of government support that can be expected for basic research, hitherto dependent on overseas grants, and whether there will be more funds for universities, which have suffered a drop of more than 30 per cent in real income over the past few years.

Peres will say no more than that he plans to "upgrade science, technology and education". How this will be reflected in Labour government budgets remains to be seen.

Nechemia Meyers

Caribbean anti-pollution plan Jamaican entente

Montego Bay, Jamaica

Temporarily forgetting their many political and cultural differences, government officials from 23 Caribbean nations met in Jamaica recently and agreed on guidelines for coordinating efforts to minimize the pollution of their seas and coastlines. The meeting was the latest in a series organized under the Regional Seas Programme of the United Nations Environment Programme (UNEP), most widely publicized of which have been those aimed at cleaning up the Mediterranean.

The plan of action agreed in Jamaica will probably have less immediate impact than the Mediterranean agreement, in part because the Caribbean is not a completely closed sea, and the level of pollution is therefore considerably lower.

Nevertheless, delegates to the Jamaican meeting stressed that the prime goal of the Caribbean plan should be preventative. According to Dr Stepan Keckes, director of the UNEP programme, "the governments have decided to tackle marine pollution not as a problem in itself but as the consequence of the problems which lie on the land".

The principal goal is to integrate concerns for the state of the marine environment into development plans for

the Caribbean region. The four projects already selected as being of top priority under the action programme include a regional oil-spill contingency plan, guidelines for managing watersheds, efforts to improve national environmental health services and broad measures to improve environmental education.

Relatively little money has been promised so far. A trust fund which is being set up as part of the action plan failed to reach its target of \$1.5 million, as a result of which UNEP secretary general Mostafa Tolba said that his organization would contribute an extra \$1.38 million. The principal donors to the fund have been Mexico, Venezuela and France, the first two being the main economic forces in the Caribbean region. Britain is prepared to make a contribution that reflects the specific interests of its dependent territories in the region (which include Antigua and the Caymans) but is unlikely to match the \$375,000 promised by France.

UNEP officials, however, as well as those from other aid bodies, hope that the plan will act as a stimulus for action at a national level. Jamaica in particular is hoping to take a leading role in coordinating development policies in the region. Addressing the closing session of the meeting, Jamaica's recently elected prime minister, Mr Edward Seaga, said that the agreement on marine pollution was "the greatest collaborative effort in the Caribbean to date, and may be a vanguard of future efforts to bond Caribbean nations in a common cause".

Jamaica is to become the base for a regional coordinating unit that will be established to facilitate the technical implementation of the action plan. The island has also put in a bid to become the home of the international sea-bed authority which would result from a successful outcome of the Law of the Sea negotiations now taking place at the United Nations in New York.

In the long term, the success of the Caribbean action plan is likely to depend primarily on procedures that individual states can be persuaded to adopt to minimize the sources of marine pollution. A top priority is to draw up a draft regional convention, and UNEP officials hope that a treaty committing countries to reducing sources of potentially damaging pollution can be agreed within two years.

The fate of the plan is also likely to be important to UNEP itself. Moves in Washington to reduce, or even eliminate, the US contribution to UNEP could cripple many of its programmes. US officials, however, are keen to cement political ties in the Caribbean — particularly with the new Jamaican government — and have indicated that the United States might in future be prepared to contribute to the trust fund. If UNEP can prove its value to the United States in the region, its medium-term prospects could be significantly improved.

David Dickson

Philosophy wrangle

Doubts persist about academic freedom in post-Tito Yugoslavia. Last month, the Yugoslav Secretariat for Information announced the reinstatement of the seven Belgrade professors of philosophy dismissed last January for their association during the early 1970s with the independent Marxist journal *Praxis*. Apparently the seven are to receive new appointments in an "Institute for Social Studies" specially created for them. Members of the group, however, say that no definite settlement has been reached.

Since *Praxis* was closed down in 1975, and the members of the group were suspended on 60 per cent salary, forbidden to teach or to publish within Yugoslavia, the authorities have repeatedly tried to persuade them to find new posts.

In June last year, the Serbian republic's law on universities was amended to permit dismissal after six months' suspension on the grounds of "damaging social interests". During the next six months, the authorities tried to persuade the suspended professors to find jobs. Two were even offered non-teaching posts within the philosophical faculty of Belgrade University, but they replied that they could not accept the post unless the other five were also reinstated.

Dismissal became effective in January, but the authorities later suggested that posts might be found in the Belgrade "Institute of Social Studies" — not part of the university but the authorities suggested that it could be rapidly converted into one.

Official plans, it turned out, envisaged that three of the group would retire, and the other four would be scattered among the existing centres of the Institute of Social Studies, covering areas such as "public opinion" and law. When these plans became known to the seven, they refused emphatically: they were, they said philosophers, and wished to work as such.

The vice-premier of Serbia, Milan Dragovic, who was acting as official negotiator, had already said that the transfer of the Institute for Social Studies to the university was nothing to do with the seven's demands, but was something that had long been necessary. He also conceded that a Centre of Philosophy within the institute would be a good idea.

On 3 April, the acting director of the institute, Dr Svetozar Culibrk, called in the whole group for talks, the first time that the authorities have been willing to negotiate with the professors *en bloc*. Dr Culibrk said that he "liked the idea" of a centre and would lay it before the institute's council. The seven are understood to be cautiously optimistic.

Vera Rich

CORRESPONDENCE

Irish evidence

SIR — Mr Peter H. Roberts's letter (*Nature* 19 March, p.184) offers the importation of infected Irish cattle as an explanation for the fluctuating incidence of bovine tuberculosis in the South West region between 1974 and 1980. It also says that the Zuckerman report carefully avoids this factor. I should like to set out the facts.

Table 10, on page 57 of the report, records the ministry's assessment of the sources of bovine tuberculosis infection in all infected cattle herds in Great Britain during 1972–1978, including imported Irish cattle. The figures for the South West and Sussex show 331 cases attributed to badgers and 4 (of which 2 were in Sussex) to imported Irish cattle. The totals for the rest of Great Britain are 0 and 171 respectively. It is little wonder therefore that Lord Zuckerman did not pursue the Irish cattle question when investigating infection in badgers in the South West.

The following breakdown of the figures for infection attributed to Irish cattle imports further detracts from the force of Mr Roberts's argument

	Great Britain	SW England
1972	59	1
1973	23	0
1974	22	0
1975	23	0
1976	23	1
1977	12	0
1978	13	0
TOTAL	175	2

Traditionally the Irish trade has been, and still is, mainly with the North-East of England and East Scotland. In the 2-year period before 1976 when, Mr Roberts suggests, cattle infected with bovine tuberculosis were imported from the Irish Republic, there was no increase in disease incidence from this source. What the figures do show is the effectiveness of the decision to introduce, in 1976, pre-export testing of Irish cattle.

W.H.G. REES

Ministry of Agriculture, Fisheries and Food,
Tolworth, Surrey, UK

Who is Nabi?

SIR — Readers may wish to know that the name of Isadore Nabi, the signatory of a recent letter criticizing my views on sociobiology and ethics (*Nature* 19 March, p.183) is fictitious. Should the writer ever make a statement over his own name, I hope he will confess that he lifted the two 1975 phrases of mine out of context in a way that reverses the meaning of one and makes it appear to contradict the other. I also trust that he will mention my later and fuller treatments of sociobiology and ethics in *On Human Nature* (1978) and *The Tanner Lectures on Human Values, Volume I* (1980).

EDWARD O. WILSON

Museum of Comparative Zoology,
Harvard University, Massachusetts, USA
Isadore Nabi is believed to be the pseudonym of Professor R.C. Lewontin of Harvard University — Editor, *Nature*.

Erratum

An incorrect spelling was given for the oak wilt fungus in the 26 March issue (*Nature* 290, p.284). The organism is *Ceratocystis fagacearum* and the beetle involved in its transfer is *Scolytus*.

Darwin's truths

SIR — The letter from your correspondents at the British Museum (Natural History) (*Nature* 12 March, p.82) relating to your editorial "Darwin's death at South Kensington" (26 February, p.735) fully supports your contention that something is amiss at that institution. The writers do not appear to understand the difference between a theory and a fact. When Darwin's *Origin of Species* was published in 1859, it was presented as a theory. It was then, and for long afterwards, proper to refer to it as "the theory of evolution". But since then the evidence for the theory has accumulated from many different sources and in many ways, among them natural and laboratory experiments. Wherever and by whatever means the theory has been tested, it has withstood every attempt at falsification.

The atom at the beginning of this century was a theory. No one today will doubt that it is a fact. Yet no one has ever seen an atom. Yet we have seen evolution in process before our very eyes in heritable changes in many forms, perhaps the most remarkable and obvious is the well-known case of industrial melanism in moths. What kind of proof do the South Kensington writers require before they will be willing to accept evolution as a fact? There are many differing theories concerning the mechanisms of evolution, and these are all to the good, but the fact of evolution as a process of change, surely, cannot be denied. The proofs for it are overwhelmingly clear.

ASHLEY MONTAGU

Department of Anthropology,
Princeton University,
New Jersey, USA

SIR — I am at a loss to understand what all the fuss is about concerning the phrase "if the theory of evolution is true". Darwin used it. I quote from *Origin of Species*:

"There is another and allied difficulty which is much more serious. I allude to the manner in which species belonging to several of the main divisions of the animal kingdom suddenly appear in the lowest fossiliferous rocks . . . If the theory of evolution be true it is indisputable that before the lowest Cambrian strata was deposited long periods elapsed as long or probably far longer than the whole interval from the Cambrian to the present day, and that during these periods the world swarmed with living creatures . . . The difficulty of assigning any good reason for the absence of vast piles of strata rich in fossils beneath the Cambrian system is very great."

This, coupled with the following quote by Dr W.R. Thompson, Fellow of the Royal Society, in the foreword of the *Origin of Species* (1956) does nothing to inspire confidence or belief in the current theories of how life started or progressed on Earth.

"It does appear to me in the first place that Darwin in the *Origin of Species* was not able to produce palaeontological evidence sufficient to prove his views, but that the evidence he did produce was adverse to them, and I may note that the position today is not notably different . . . As we know there is a great divergence of opinion among biologists not only about

the causes of evolution but even about the actual process, the divergence exists because the evidence is unsatisfactory and does not permit any certain conclusions."

I am left wondering which theory requires the most blind faith.

GORDON SMITH

Liverpool, UK

Room for all

SIR — At first amused, I am now saddened by the "Death of Darwin" controversy (*Nature*, 26 February, p.735 *et seq.*). We have slipped back a hundred years: how long before letters signed Wilberforce and Huxley appear? Why "either-or"? Why cut off either right or left hands? Is there not room for Darwin, Hennig, God — and even Marx?

J.R. BAKER

Cambridge, UK

Popper's philosophy

SIR — Accusations that museum displays organized in the light of cladistic philosophy represent creeping Marxist-Leninism were bad enough. But when *Nature* sees fit to defend the scientific status of Darwinism on the grounds that "metaphysical theories are not necessarily bad theories"¹ then matters philosophical have truly gotten out of hand.

It should come as no surprise to those familiar with the writings of various cladists that the writings of Professor Popper on evolutionary theory are held in great esteem. After all, he has argued for years that no view of history, whether human, biological or technological, admits of the classification scientific. For Popper the events of history are unique and, thus, not amenable to systematic explanation via theories of any sort². Since cladists find the infusion of the least amount of theoretical insight into classification suspect in much the same way that their positivistically minded cousins, the phoneticists, did a decade or so ago, it is hardly surprising that they would greet the rediscovery of Professor Popper's writings from the 1940s and 1950s with great glee.

Popper's hostility to evolutionary theory explains the favour his views receive from systematists fond of cladism. But it does not explain why this same hostility should inform the judgments others make of the scientific status of Darwinism. Popper's views have been roundly and soundly criticized by numerous philosophers interested in the scientific status of evolutionary theory. The apparently timeless contentions that the theory is (1) tautologous, (2) unfalsifiable, (3) lacks predictive power and (4) lacks confirmation have shown to be false by a decade of scholarship in the philosophy of biology dating from the appearance of David Hull's *Philosophy of Biological Science*^{3,4}. Why *Nature* should choose the cladists' favourite philosophical authority over the ruminations of contemporary authors gives one pause not about politics but about the reading habits of the scientific community.

There are numerous reasons for not taking Professor Popper's criterion of demarcation of science and non-science seriously. Perhaps the most obvious is that it just does not cut well — cosmology and evolutionary theory wind up in the metaphysical hopper, astrology

and phrenology make the grade as science — false science but nevertheless science.

Numerous other contributors to the philosophy of science such as Nagel, Hempel, Hanson, Toulmin, Kuhn, Shapere, Lakatos, McMullin and many others have shown serious conceptual flaws in Popper's defence of the falsifiability criterion for demarcating science from non-science⁵.

Since the issue is so badly mauled in the *Nature* editorial let us take up the matter of the falsifiability of Darwinism since it seems of such great concern to cladists, creationists, and correspondents to this journal. The issue is stated as the question, "Is Darwinism falsifiable?" admits of a simple answer — yes.

If we are talking about the version of evolutionary theory propounded by Darwin in the *Origin*, then that theory has been shown false many times over. It claimed that all organic variation could be accounted for by natural selection and a tendency to inherit among all creatures. This is false. Mutation and recombination at the level of genes refute the adequacy of Darwin's posited mechanisms. Darwin claimed that the bulk of speciation occurred through anagenesis — evolution within a lineage. This is false. Cladogenesis or the splitting of an interbreeding population into two groups via natural barriers or other means accounts for the bulk of speciation. Darwin claimed that social behaviour exists in insects as a consequence of group benefit. This is false. Social behaviour exists among many insects as a consequence of kin selection, reciprocal altruism, parental manipulation or some combination of these mechanisms. This list could go on. The point is that evolutionary theory, like all theories in science is constantly tested, refined, modified, adapted and re-written. The issue confronting defenders of the validity and utility of evolutionary theory in its early or modern forms is not whether it is science or not — Darwin himself certainly settled that matter with admirable skill in the empirical and analogical evidence he brought forward in his own writings. Rather the question is how does one go about invalidating scientific theories that constantly change and evolve — an issue that ought to attract the attention of the cladists if not the creationists.

How true is the theory of evolution? It is as true a theory as there is in science. Which is to say it depends on who is asking and when. Of course the theory of evolution is not a fact. Evolution is a fact and the theory of evolution tries to explain this fact. But the theory of evolution surely passes muster as science, even on the out-dated grounds cited by Professor Popper in his early work. (Even he no longer believes in the adequacy of his early analyses of evolutionary theory⁷.) The real question that should concern scientists is whether they know enough about current thinking in the history and philosophy of science to know a sound theory when it stares them in the face — a circumstance unlikely to occur at the British Museum unless this ignorance is alleviated.

Academia stagnant?

SIR — I see no reason for your concern (*Nature* 19 March, p.175) about the ability of British universities to recruit young scientists to academic posts. The present policy of recruiting young persons in their mid-twenties and sometimes without postdoctoral or international experience has so little merit that nothing would be lost if this recruitment of lecturers was totally ended. The best of our young scientists will wish to stay longer in full-time research and will continue to be available to the universities for years to come.

The rapid recruitment of academic staff in the 1960s expansion phase is unlikely to be the cause of stagnation in science departments. Where stagnation exists it is fairly certain that the department has defective leadership which might very well result from easy promotions gained in the years of expansion. Universities should, especially when resources are tight, recruit scientists into permanent teaching posts later in their careers than has been customary in Britain. A changed policy could provide continuing opportunities for the present generation of young scientists. Retirements and early retirements will improve some departments and at the same time allow new entrants or well justified internal promotions which ought to maintain the intellectual vitality of any department worth keeping.

Freedom from NATO

SIR — With the mounting concern in your columns on measures which scientists should take to ensure academic freedom for colleagues deprived of their rights, it is surprising that you publicize the NATO Advanced Study Institutes, that scientists are happy to perform on the stage which NATO sets, and that no mention of this paradox has been made in your correspondence.

No doubt these conferences fulfil a useful scientific function in promoting exchange of information in very congenial surroundings. Under normal circumstances, the argument that funds (from a rather dubious source) were being channelled to a good cause would have been sufficient to rationalize the situation. In some cases there is also the hope that the opinions of the scientific community will filter back along this channel, and that contact with sensitive institutions will lead to a more extensive dialogue and to a greater opportunity for diplomatic manoeuvres. Often, such occasions bring us into contact with scientists who have difficulty in meeting foreign workers because of governmental restrictions.

These conditions do not apply to attendance at NATO-supported conferences. There is little evidence that the meetings provide a forum for discussion with NATO officials in any way which would allow scientists to exercise their social responsibility. Nor could it be claimed that the activities of the conferences could not easily take place under other auspices. But most seriously, at a time when nuclear installations in Europe, products of scientific ingenuity, threaten the peace of our own and other countries, this close relationship between scientists and NATO can only be seen from outside as complete approval for (if not connivance with) the increasingly military orientation of our society.

This association with NATO must also affect the scientists themselves. After participation in any symposium it is difficult to leave without feeling some debt of gratitude to the organizers who lavish money and attention on their charges. Qualms about the ethics of the institution running it are henceforth stifled. Thus the NATO scientific conference is a highly effective public relations exercise both for the participants, and those who look to scientists for a lead in problems created by technology. How can Soviet colleagues be expected to take our views seriously when they see the strength of our opinions so cunningly controlled by political agencies? If our protests are to carry conviction in any field, we should dissociate ourselves from the influence of organizations like NATO, and take every opportunity to make this known publicly. ROGER R.C. University of Liverpool, UK

Conservation sites

SIR — Many criticisms can be levelled at the system of Sites of Special Scientific Interest (SSSIs) but Muir's arguments (*Nature* 12 March p.82) are untenable.

Extinction may be "normal" but that is irrelevant to "value". To analogize, we will all die, but do not usually accept this as an excuse for murder. We are replacing complex ecosystems with much simpler landscapes, allowing for fewer species to exist or appear.

In a limited sense, rarity may support a value judgement of "biological deficiency", and the mere presence of a rarity may be poor grounds for conservation; but rare species can be good indicators of environmental quality when considered along with other evidence.

SSSI status may result in a "loss of freedom" of the owner. Losing such sites is a far greater "loss of freedom": it destroys our options and those of future generations, for we cannot replace them.

It is also misleading to allege just that protection of SSSIs is a cost to their owners: it prevents owners *increasing* their income by reclaiming the site, but that increase would itself be a cost to the taxpayer in terms of grants for reclamation, and later subsidies.

It is astonishing that someone from a university zoology department could contend that "Once . . . information is recorded and published . . . nothing new will be learned by preservation". No complete record of any site or habitat exists, and the same material can generate an infinite variety of "descriptions". Frequently we cannot turn to the literature for basic data to test new theories — we have to test them through fresh fieldwork designed specifically for that purpose. If we lose the field sites, ecology becomes metaphysics and not science, and to rely just on the environments we are creating today leaves us a severely restricted data base.

This necessity has fortunately been recognized in other fields. Once, excavators of bone caves destroyed vast storehouses of information by removing every vestige of material but failing to distinguish stratified deposits. Later workers recognized strata but again lost vital information by failing to extract pollen, rodent bones, and other small items. Now sections of deposit are left undisturbed for the future application of new ideas and techniques. Ecologists need similar opportunities.

NEWS AND VIEWS

Genes of lymphocytes I: Diverse means to antibody diversity

from Miranda Robertson

AFTER fifteen years of controversy and five years of DNA cloning, immunologists are at last unanimous on how antibody diversity is generated. This remarkable eventuality is due to the accumulation over the past five years of evidence for almost every mechanism anyone has ever suggested; and to which has now been added yet another, of such baroque complexity that it could never have occurred to anyone to suggest it but for the evidence (albeit preliminary) in the DNA.

There used to be, broadly, three schools of thought, one of which adopted the extreme position that the entire antibody repertoire was encoded in a vast array of germ-line genes, and the other two of which favoured the somatic generation of variation on the basis of a limited number of germ-line genes. Two means were proposed for the somatic generation of variation. One was simple point mutation; but this on its own would not explain the distribution of the variation, which is concentrated in three "hypervariable" regions on the variable region gene (see Fig. 1). The other was recombination, represented in its most elegant and extreme form by the mini-gene theory of Kabat, who proposed that a range of genes coding for each of the three hyper-variable regions and the four less variable (framework) regions existed separately in the genome, to be brought together in variable combinations during the differentiation of the B lymphocyte. This theory however did not explain the evidence for point mutations in the framework regions. All these views have now been at least partly vindicated, as became clear at the massive immunology symposium in Paris last summer¹; and at a more recent and smaller symposium in Salt Lake City*, their proponents were still reeling with surprise at finding they no longer had anything to quarrel about.

Two things became clear very soon after the cloning and sequencing of the first immunoglobulin genes. First, there is quite a large number of germ-line genes: more than one for each of the known variable region subgroups (a subgroup is a family of

variable regions defined by similarity in the framework regions). Estimates have been made for mouse λ and κ light chain genes. Whereas the mouse λ V gene family contains only two genes², S. Cory (Walter and Eliza Hall Institute, Melbourne) now puts the size of the κ gene family at between 100 and 300; however, less is known about the possible numbers of heavy-chain variable region genes which she and her colleagues are in the process of investigating.

Second, the differentiation of a B lymphocyte is accompanied by the translocation of V region DNA. In the case of the light chain, one of the germ-line V genes, comprising the first three framework segments with two hypervariable regions and part of the third, is brought into proximity with one of a cluster of J genes comprising the rest of the third hypervariable region and the fourth framework segment. Since V genes may recombine with J genes at random, and with variation in the site of the join, this immediately generates considerable diversity. The scope for diversification is even greater in the case of the heavy-chain

genes, in which the V gene, which extends only to the end of the third framework region, recombines with a D gene comprising the third hypervariable region, and the D in turn recombines with one of a cluster of J genes coding for the fourth framework region. The D and J heavy-chain genes thus behave very much like the mini-genes postulated by Kabat; but Kabat never dreamed of the extraordinary properties of D genes that are beginning to emerge from the latest investigations of S. Tonegawa and his colleagues (Basel Institute of Immunology).

They have used a D region probe² to locate a cluster of eight homologous D genes in germ-line DNA. All eight genes are 17 base-pairs long; yet expressed D regions with substantial "core" homology to the germ-line genes range from thirteen to more than 40 base-pairs in length. This is too extreme to be explained by variations in the site of V-D-J recombination. Tonegawa has suggested that the explanation may lie in D-D joining, by a mechanism that would not result in simple tandem repetition of the homologous sequences. The mechanism depends on the

Fig 1. Immunoglobulin molecules are made up of four chains: one pair of heavy chains and one pair of light chains. Each chain is divided functionally into two regions: the variable region, which mediates antigen recognition, and the constant region, which in the case of the heavy chains mediates the effector function of the molecule.

The variable region can be further subdivided into four regions which vary only slightly from one antibody molecule to another, and are known as the framework regions, and three regions (the hypervariable regions) which are very much more variable and in the folded protein form the actual antigen-binding site.

Each light chain is now known to be coded by three separate genes: a C gene coding for the constant region, a J gene coding for the fourth framework region and part of the third hypervariable region, and a V gene coding for the first three framework regions including hypervariable regions one and two and part of hypervariable region three.

Each heavy chain is coded by four separate genes: a C gene coding for the constant region, a J gene coding for the fourth framework region, a D gene coding for the third hypervariable region, and a V gene coding for the first three framework regions including hypervariable regions one and two.

Miranda Robertson is associate editor of Nature.

*The ICN/UCLA Symposium on *Immunoglobulin Idiotypes and their Expression* was held in Salt Lake City, Utah, on February 8-15, 1981.

Fig. 2 The pattern of genomic sequences believed to mediate V-J and V-D-J joining in light (a) and heavy (b and c) chain variable region genes. Open rectangles are coding sequences, shaded rectangles are nonamer and heptamer signal sequences, and intervening lines are non-coding DNA. The figures 12 and 23 on the non-coding DNA refer to the length of the spacer regions between the heptamer and the nonamer, which are highly conserved sequences believed to act as recombination signals: the heptamer is followed by the nonamer after a space of 12 (strictly, 11 or 12) base pairs downstream of the V_L gene, and inversely, the nonamer is followed by the heptamer after a space of 23 (strictly, 22 or 24) base pairs upstream of the J_L gene (Fig. 2 a). Heavy-chain V genes are followed by the same signal sequences with the 23 spacer, and heavy-chain J genes are preceded by the inverse signal, again with a 23 spacer (Fig. 2 b). Early *et al.*⁴ and Sakano *et al.*⁵ surmised that recombination depends on the pairing of the signal sequences plus a 12-base-pair spacer with the inverse signal sequences plus a 23-base-pair spacer; they accordingly predicted that D_H genes should be flanked by signals with 12-base-pair spacers (Fig. 2 c). This has proved to be the case². If the 12/23 rule holds, however, it should make D-D joining impossible; and that is where the baroque complexity comes in.

Tonegawa and Kurosawa have proposed that each D region can treat the central 7 of its 17 base-pairs as the heptamer of the signal sequences and add the five coding base-pairs plus their adjoining heptamer, either upstream of downstream, to the adjoining spacer to make a 24 instead of a 12 base-pair spacer (Fig. 2 d). This would make it possible to add about 5 base-pairs of one D gene to another without violating the 12/23 (or 12/24) rule or producing tandem repeats, which are not found.

12/23 rule first enunciated by Early *et al.*³ for V-J recombination, and is described in detail in the legend to Fig. 2.

Even without D-D joining, the evidence for which is at best circumstantial, the recombination of a substantial repertoire of V genes at random with J and D genes would be sufficient to account for an antigen-binding repertoire well into the thousands. To this variation within chains must be added the variation generated by the association of different light chains with a given heavy chain. Since the expression of the heavy-chain genes precedes that of the light-chain genes, it has been assumed that each different heavy chain associates with a different light chain in the progeny of a single pre-B cell⁶. By fusing a pre-B cell line with a myeloma line that does not express L chains, W. M. Kuehl and his colleagues (Virginia University) have succeeded in inducing the expression of light chain genes of the pre-B cell and demonstrated that different rearrangements of the κ genes do in fact occur in the progeny⁷.

Finally, there is growing evidence for further diversification of the rearranged immunoglobulin genes by somatic mutation in the course of B cell ontogeny. In the absence of a B cell line whose ontogeny can be followed *in vitro*, the evidence is necessarily indirect. But the availability of cloned germ-line genes for

the V-regions of some antibodies has made it possible to compare the germ-line sequences with those of secreted immunoglobulins from B cells at different stages of maturation. At early stages of maturation, B cells synthesize immunoglobulin M; at later stages they synthesize immunoglobulins of other classes: IgG, IgA or IgE. Thus by comparing IgM and (say) IgG in turn with the homologous germ-line sequence, it is possible to detect any increase in departures from the germ-line gene that may have occurred as the cells switched from one class of immunoglobulin to the next.

Such increases have been reported both by A. Bothwell (Massachusetts Institute for Technology) and from the laboratory of L. Hood (California Institute of Technology), working with antibodies raised against nitrophenol (NP) and phosphorylcholine (PC) respectively. Antibodies raised against these antigens possess, in certain strains of mouse, the interesting and useful property that a very high proportion of the total immunoglobulin bears a characteristic antigenic determinant, or idio type, of its own (NP^b in the case of anti-NP antibodies, and T15 in the case of anti-PC antibodies). But not all even of those antibodies bearing the same idio type are by any means identical, and in the light of recent analyses this is hardly surprising. Both Bothwell⁷ and

Hood report that there is a cluster of several germ-line V genes all with substantial homology to the idio type-bearing anti-NP and anti-PC proteins. The existence of such homologous V-gene clusters (as well as Tonegawa's homologous D gene clusters) strongly suggests duplication of genes during evolution — particularly since two of the five homologous genes sequenced by Hood and his collaborators are actually identical.

As it turns out, comparison of the partial amino-acid sequences of several T15 proteins with the germ-line sequences shows that all the proteins are derived from the two identical germ-line genes, but with numerous substitutions, notably in the proteins of ontogenetically later classes (IgG and IgA)⁸. None of these substitutions can be explained except by mutation, with one exception which could (but need not) be due to recombination between two of the germ-line V genes.

The sum of all these recent data leaves us with an embarrassing riches of diversity-generating mechanisms, but some important outstanding questions about their deployment. The first and most obvious is exactly how many germ-line genes there are. It is believed that there are four functional J genes each for the light and heavy chains; but estimates of the numbers of V genes still range between 500 and 1,000, and little is known of the total size of the D-gene family, of which that sequenced by Tonegawa and his associates may represent only a branch.

The second and more challenging is whether a special mechanism, still undiscovered, is needed to explain the concentration of amino-acid substitutions in the hypervariable regions. Both germ-line sequence and somatic recombination go some way towards explaining this pattern of variation. Related germ-line genes differ from one another more in the hypervariable regions than in framework-coding regions; and variable V-J and V-D-J joining account for further variation in the third hypervariable region — particularly in the case of V-D-J joining. But Gearhart *et al.*⁸ have shown that somatic mutations too are clustered, at hypervariable regions 1 and 2.

This could in principle be explained without recourse to further special mechanisms, simply by somatic selection. B cells whose surface immunoglobulin does not bind antigen produce no progeny: thus those expressing mutations in the hypervariable regions which form the antigen-binding site will tend to be selected. Selection will also occasionally operate on mutations affecting framework sequences: although it is the hypervariable regions that actually make contact with antigen, the framework regions may influence the manner in which they do so — for example, framework variants of an immunoglobulin which in its original form bound PC both on its own and complexed to a carrier will no longer bind the PC-

carrier complex (M D Scharff, Albert Einstein College of Medicine) Both the clustered substitutions in the hypervariable regions, and the occasional ones in the framework can therefore be accounted for by selection for antigen binding

It would be a mistake however to assume that all mutations in expressed immunoglobulin genes must have been specifically selected indeed, some are silent and could never have been subjected to selection These are presumably the "neutral mutations" of the immune system But if the pattern of mutations requires no special explanation, it is possible that the rate of mutation may Certainly many immunologists are wondering about possible mutagenic reactions associated with the class switch Notwithstanding the considerable difficulties associated with the elucidation of molecular mechanisms of immunoglobulin gene rearrangement,

the issue of mutation rate may be resolved more quickly by research at this level than by arguments about sequences, because arguments about the mutation and selection of sequences depend on a detailed understanding of the relationship between the sequence of an immunoglobulin and its antigenbinding properties and this is usually unknown

However, each antibody molecule can now be seen as the end product of a series of selective steps, beginning with the germ-line genes The germ-line V, J and D genes have presumably been selected in the course of evolution for their ability to produce proteins that will bind to common environmental antigens There follow at least two rounds of somatic selection by antigen The first acts on the V-J and V-D-J recombinations that produce IgM It is followed by at least one more round of somatic selection favouring mutations that produce efficient binding to the same antigen, or indeed to any other antigen present in large enough quantities to encounter the mutant cell A detailed analysis of hybridoma proteins from immunized and hyperimmunized mice, such as Bothwell and his colleagues have already begun, may help to show how far antigenic selection could account for the range of antibodies a single mouse is able to produce against a single antigen

coupled with the missing oceanic crust, arising from Earth expansion during the late Proterozoic Pure Earth expansion has the effect of leaving continental centres in the same coordinate position and so has no effect on the polar wandering paths The problem is to see how the relative continental motions during the Phanerozoic, which palaeomagnetism brings out so clearly, could have returned the continents to the relative positions they had in the Proterozoic

The main counter-arguments to expansion were the well known length of day calculation (Runcorn *Nature* 204, 823, 1964) based on daily and annual growth increments in corals, the lack of secular change in global sea level over the Phanerozoic (Vail *et al Mem Am Ass petrol Geol* 26, 83, 1977) coupled with near stability in the volume of the hydrosphere (Anderson *Rev Geophys Space Phys* 13, 37, 1975), and my demonstration that for the past 5 years, half or more of the subduction required by plate tectonics on an Earth of fixed radius is actually occurring These arguments give a maximum rate of change in Earth radius of 0.1 cm yr⁻¹ since the Devonian, in gross conflict with the idea of accelerating expansion during the late Phanerozoic This conclusion is backed up by the provinciality of Palaeozoic faunas, pointed out by Clive Burrett, which suggests that major ocean basins existed at that time

All this, however, fails to provide any hard evidence about palaeoradius in the Proterozoic, to which attention is now focused Only Stewart's (*J geol Soc Lond* 133, 281, 1977) palaeogravity method, which compares computed geotherms with mineralogical evidence for the actual *P-T* conditions in the crust and upper mantle, gives any help here Palaeoradius can easily be calculated from the surface gravity field provided that Earth mass and the universal constant of gravitation are known Gravity seems to have remained within a factor of two of its present value throughout Earth history, implying a rate of change in radius < 0.1 cm yr⁻¹ and hence limiting late Proterozoic expansion to < 1,000 km This is too small by a factor of 2.5 to solve the problem of the missing oceanic crust

It is to be hoped that the basically sound palaeomagnetic technique for measuring palaeoradius will soon be applied to early Proterozoic basic dykes across a stable continent such as Canada Using samples collected specifically for the purpose, it should be possible to reach a definite decision about the likelihood of late Proterozoic Earth expansion Published palaeoradius estimates using the palaeomagnetic technique have always used samples from Phanerozoic rocks and even these, it was pointed out at the meeting, did not always come from stable continental areas as required by theory, so that the validity of the palaeoradii was open to doubt □

The expanding Earth

from A. D. Stewart

TWENTY-FIVE years ago the University of Tasmania hosted a conference on continental drift organized by Professor S. W. Carey, at which he presented his now famous review documenting the detailed geological evidence for continental break-up and separation during the Mesozoic and Cenozoic, with explanations for major Earth structures like oroclines (hair-pin bends in mountain belts) and sphenochasms (wedge-shaped oceanic areas like the Bay of Biscay) thrown in for good measure Most of Carey's views on inter- and intracontinental motions are now, of course, generally accepted but the basic mechanism he postulated — Earth expansion sufficient to have generated all ocean basins since the Palaeozoic — engenders in most geologists the same feelings of incredulity that continental drift did 25 years ago

February 1981 saw the sequel to the Tasmanian meeting — the Expanding Earth Symposium at the University of Sydney, again organized by Carey — at which two new lines of evidence supporting major Earth expansion were discussed The first was the work of Andy Glikson

(*Geology* 7, 449, 1979) which highlights the lack of geochemical evidence for oceanic crust, or indeed any mantle-derived crust, surviving from the Proterozoic, and the palaeomagnetic and stratigraphical evidence for continental integrity over this period This was backed up by Keith Crook's analysis of the global abundance of ophiolites and turbidites, both generally accepted indicators of oceanic crust Their abundance decreases exponentially with increasing age back to the end of the Proterozoic (~ 10⁹ years ago) when they disappear completely from the geological record This is not just a sampling effect because turbidite sediments are well known from the Archaean (> 2.5 × 10⁹ yr) Crook's interpretation of these data is similar to Glikson's — there were no ocean basins in the Proterozoic because the Earth had only about 60 per cent of its present radius

The second new line of evidence favouring expansion comes from palaeomagnetism Embleton and co-workers (*J Geophys* 49, 20, 1981) showed that for quite long periods during the Proterozoic, continental blocks such as North America and Australia in their present relative positions had common polar wandering paths They interpret this surprising result,

A. D. Stewart is in the Department of Geology at Reading University

Plesiosaurs — rigging and ballasting

from Michael A Taylor

ALTHOUGH plesiosaurs were among the dominant marine reptiles of the Mesozoic era, it was difficult to see how they hunted their prey for they had large air-filled lungs and would have been too buoyant to dive underwater easily. In a recent paper D G Darby and R.W Ojakangas (*J. Paleont* 54, 548; 1980) suggest that plesiosaurs neutralised their upward buoyancy by swallowing masses of pebbles and retaining them in their stomachs in much the same way as modern crocodiles do.

At one time it was thought that the stomach stones of crocodiles and plesiosaurs helped in grinding food in the stomach. Darby and Ojakangas draw attention to the work of H B Cott (*Zool Soc London Trans* 29, 211, 1961) who found fragile but unpulverised bones and shells of prey along with stones in crocodile stomachs. He went on to show that crocodiles swallow stones to use as ballast so they can lie hidden under the river surface with only the eyes and nostrils protruding above water, until some prey animal comes close enough to be taken. Crocodiles can also lie on the river bottom lodged against the current. The mass of pebbles lying forward in the belly stabilises the animal in roll about the longitudinal axis, like the keel of a boat, and corrects its tailheaviness allowing it to lie horizontal in the water. The weight of the pebbles also helps the crocodile to drag large prey underwater so that they can be drowned. Darby and Ojakangas point out that stones and unpulverised prey have also been seen in a fossil plesiosaur (B Brown *Science* 20, 184; 1904) and so conclude that plesiosaurs also used their stomach stones for ballast.

Their conclusion has implications for our ideas of the hunting strategies of plesiosaurs. If they neutralised virtually all their upward buoyancy, they could stay dived without using much limb action, in contrast to the extinct ichthyosaurs and modern whales which have no stomach stones, but are always on the move when looking for prey and can produce a compensating downthrust with their fins. One group of plesiosaurs, the plesiosauroids, had small heads on exceedingly long necks which gave the animals a most unstreamlined shape and perhaps made them too slow to pursue prey in open water. One wonders if they lurked in ambush, or searched slowly over the bottom ready to strike out their necks at any passing prey. The other main group of plesiosaurs, the pliosauroids, were large carnivores perhaps comparable with the modern killer and sperm whales. They may

Fig 1 Representatives of the two main groups of plesiosaurs A, the pliosauroid *Liopleurodon* (~11m), B, the plesiosauroid *Muraenosaurus* (~5m) (after Robinson 1975)

have hid unmoving till prey came near enough to be run down in a short sprint, but they were quite streamlined with their large heads and short necks and might equally have been open-water cruising predators. Confirmation of these hypotheses must wait for an analysis of the functional anatomy of the head and neck of these forms (see Fig 1).

Darby and Ojakangas also recovered stomach stones from a plesiosaur found in the Upper Cretaceous of Montana and concluded from an analysis of the shapes of the pebbles that they were collected in an estuary rather than from a shingle beach. It does indeed seem likely that plesiosaurs would forage in the sheltered and productive tidal waters of an estuary rather than off an exposed and comparatively foodless beach. The plesiosaur may, however, have tended to select certain shapes of pebble, so that its stomach stones may not necessarily be a reliable guide to their source.

The structure and function of the distinctively domed body, sprouting four large broad-bladed limbs, has itself been

Fig 2 Plesiosaur limbs worked like those of turtles, shown here. The hydrofoil surfaces swept up and down producing lift forces L_u and L_d which averaged out over the cycle to a forwardly directed propulsive resultant force R as shown in the parallelogram of forces (after Robinson 1975)

the subject of an elegant analysis in recent years (*N. Jb. Geol. Palaont. Abh.* 149, 286; 1975 and 153, 86, 1977).

Jane Ann Robinson distinguishes between rowing and underwater 'flying' as the two possible modes of action of the limbs. These two modes differ radically in limb form and action. In the power stroke of a rowing action, the limb sweeps backwards, while its vertically aligned blade bites into the water and levers the animal forwards. The limb then returns forward to start another power stroke. A limb which is adapted to rowing is therefore rigid and oar-shaped, broadening at the end, and moves in the horizontal plane. The limb of a plesiosaur is of quite different design and has the characteristic adaptations to underwater flight. The limb is flat with an aerofoil (or hydrofoil) cross-section so that when it moves through the water with the plane of the limb edge-on to the direction of motion through the water it generates a lift force. This lift force is perpendicular to the plane of the limb and its direction of motion through the water. The plesiosaur limb has therefore to move in the vertical plane to produce the horizontally and forwardly directed propulsive force, unlike a rowing limb which moves in the horizontal plane (see Fig 2). The plesiosaur limb tapers towards its tip to reduce drag, unlike the oar-like shape of the rowing limb. The plesiosaur limb has just enough flexibility to allow trimming and to damp out drag-producing eddies, which is, again, quite unlike the rowing limb which is rigid and relies on its production of drag to bite into the water and thus gain leverage and efficacy. Indeed, the limbs of plesiosaurs share these features with the forelimbs of marine turtles, seals and penguins, which all act as hydrofoils. Robinson has therefore been able to base her reconstruction of plesiosaur limb action

Michael A Taylor is in the University Museum, Oxford

Fig. 3 The shoulder and hip girdles were suspended within the ventral basket which was held under the vertebral column like the string in an archer's bow. This elastic suspension could absorb the up-and-down motion of the limb girdles at each beat of the limbs, while transmitting the propulsive force to the body. A and B, side views of the body, C is a plan view of the ventral basket (after Robinson 1977)

partly on the action of the forelimbs in these modern animals

The distinctive shoulder and hip girdles of plesiosaurs were broad, flat bony plates with limb joints on opposite edges. The main propulsive muscle masses lay on top and under the girdles, and their tendons attached to the dorsal and ventral surfaces of the limbs and swept them powerfully upwards and downwards. Supplementary muscles controlled the trim of the wings so that on both up- and down-stroke the hydrofoil surfaces of the limbs, moving in the vertical plane, generated a resultant 'time-averaged' lift force forwards. Effectively, therefore, each pair of limbs mounted on its girdle was a self-contained power unit producing a forwardly directed propulsive force.

How were the two 'power modules' supported within the domed body, so as to transmit the propulsive forces? Plesiosaurs had a distinctive 'ventral basket' made up from the two limb girdles bound together by ligaments running onto and between the gastralia, the splint-like bones of the middle abdominal floor. Robinson shows that this acted as a string to the 'archer's bow' formed by the vertebral column. The contraction of the muscles between the dorsal processes of the vertebrae bent the ends of the column upwards and pulled taut the ventral basket suspended from the vertebral column by its ligamentous attachments. With the ribs, this formed a remarkable suspension system restraining the girdles while allowing some elasticity to absorb the up-and-down motion of the girdles with each beat of the limbs (see Fig 3). The ability to vary independently the

action of each limb would be most useful, as it made possible rapid changes of direction in pursuit of prey, or when diving from a position at the surface. The propulsive forces of the four limbs would then be asymmetric in magnitude and direction, but they could still be sustained by the girdle support system. One can also conclude that the plesiosaurs could move and breed on land, *pace* Robinson, as the arched vertebral column prevented the collapse of the lungs. Ichthyosaurs and modern whales cannot move on land and therefore give birth in the water to live young; certainly, there are specimens of ichthyosaurs — but not plesiosaurs — with unborn young still in the body cavity. Plesiosaurs may have given birth to live young or laid eggs in pits scraped out with their tails, like modern turtles.

The plesiosaur tail was not very long and part of it was taken up in the 'archer's bow' system. The tail vertebrae bear no evidence of the attachment of a substantial propulsive tailfin — which would not be needed, with four powerful limbs — but plesiosaurs did have small vertical tailfins, presumably used for stabilising the animal directionally and for controlling direction of motion.

The limb and body plan of plesiosaurs, so uniform within the group, is radically different in form and function from the original terrestrial reptilian plan, which was adapted to support the body against the vertical pull of gravity while walking on land. The nothosaurs of the Triassic were small marine carnivores not very different in body or limbs from the terrestrial reptiles. However, the rare nothosaur *Pistosaurus* is morphologically intermediate between other nothosaurs and plesiosaurs and is presumably closely related to the ancestors of plesiosaurs. Nobody has as yet done an analysis of these animals comparable to Robinson's work and so we do not know when the characteristic locomotor pattern of plesiosaurs actually evolved. The plesiosaurs diverged rapidly into their variously adapted lineages at the very start of the Jurassic, in a good example of the macroevolutionary concept of 'adaptive radiation'. Did this event coincide with, and was it caused by the full development of the plesiosaur locomotor plan, or was there some other factor, such as the mass extinction of potential competitors, which allowed the plesiosaurs to exploit the potential of a previously evolved locomotor plan? □

Strategies of viral oncogenesis

from John Wyke

STUDIES on the molecular mechanisms of neoplasia by oncogenic RNA viruses (retroviruses) have in the past concentrated on agents that transform cells in tissue culture. These viruses contain genetic information, oncogenes, that seem essential for the induction and/or maintenance of cell transformation and that are distinct from the genes required for virus replication. Viral oncogenes are believed to be derived from the homologous sequences, present in normal vertebrate cells, that were presumably acquired by the viruses during their evolution. Their reintroduction into the cell under the control of viral transcriptional promoters leads to aberrant oncogene expression and resultant cell neoplasia.

Attention has recently turned to the many retroviruses that do not transform cells in available tissue culture systems but nonetheless induce tumours in animals. These viruses seem to possess only those genes needed for their replication. Without specific oncogenes, how do they induce neoplasia? There are, *a priori*, several possibilities: (1) expression of viral replicative genes themselves may directly or indirectly alter cell growth, (2) since the DNA copy of the retroviral genome, the

provirus, integrates into the cell DNA, it may act as an insertional mutagen, its presence disrupting normal cell gene expression, or (3) the inserted provirus may subvert functions more specifically, by placing particular cell genes under the influence of viral promoters. Two recent papers^{1,2} provide evidence for the last possibility from the avian lymphoid leukaemia viruses (ALV).

Both studies have taken a similar approach, based on recent understanding of the nuances of provirus structure and function that are summarized in the diagram. The coding sequences in the viral RNA (*gag-pol-env* in diagram) are flanked by 5' and 3' unique segments, U5 and U3, and a short terminal redundancy, R. These are thought to be involved in synthesis of viral DNA which eventually becomes integrated as a linear provirus (shown in diagram). The proviral DNA is longer than the parent RNA, U3 being repeated at the 5' end with U5 duplicated at the 3' end of the molecule. The viral genes are thus bounded at each end of the provirus by a long terminal repeat (LTR) sequence, comprising the regions U3-R-U5. Sequencing and *in vitro* transcription studies indicate that U3 contains a putative promoter sequence, and the promoter in the left-hand LTR is thought to direct transcription of progeny viral RNA. Because of the redundancy of the LTR

John Wyke is in the Tumour Virology Laboratory, Imperial Cancer Research Fund Laboratories, London

there is also a promoter at the right-hand end of the integrated provirus that seems to have no role in the viral life cycle. However, preliminary evidence indicated that it might also be active and occasionally direct transcription into neighbouring host DNA sequences³.

Starting from this point, Payne *et al*¹ and Neel *et al*² investigated integrated provirus structure and function in a number of advanced lymphomas induced in chickens by several different ALV. They drew the following conclusions: (1) The cells from individual tumours showed provirus integration at identifiable sites. This suggested that the tumours arose largely, if not entirely, from a single infected cell, implying that tumour induction is a rare event. Although many tumours contained several proviruses, those which carried only a single provirus were most useful for further interpretation. (2) Tumours from different birds often showed similarities in the sites of provirus integration. This evidence for tumour-specific integration sites was not strong but was significant in view of the many previous studies showing that proviruses are able to integrate at numerous, perhaps even random, locations. (3) Many tumours contained incomplete proviruses even when only one provirus was present (these latter cells did not contain normal viral RNA species). Thus viral replicative functions are not needed for the maintenance of neoplasia, indeed, immune mechanisms directed against viral antigens might favour the survival of cells whose proviruses do not direct the synthesis of viral proteins. (4) All tumours contained at least one LTR. (5) All tumours contained virus-related RNAs that possessed too little virus-specific material to be revealed by a probe representing the whole provirus but could be detected with a probe for the R-U5 sequences. These RNAs, which fall into only two or three size classes, were expressed at a high level and are thought to represent transcription initiated in a viral LTR (and hence containing U5 sequences) and continued into downstream host sequences (see diagram).

On the basis of these findings Payne *et al* and Neel *et al* propose that ALV cause tumours by inserting a viral LTR, containing a promoter, adjacent to cell sequences that are then expressed under viral control. The evidence for proviral integration in a specific region of the cell DNA and the limited number of size classes of RNA found among virus-related transcripts suggested that viral promoter insertion might lead to neoplasia only if it occurred near one or a few appropriate cell genes.

This possibility was pursued by Hayward *et al* (see *Nature* April 9, 290; 475, 1981), who reasoned that ALV might 'switch on' the cell homologues of the known oncogenes of transforming retroviruses. Accordingly, they screened lymphoma

RNA with cDNA probes specific for five different viral oncogenes. In general, there was no enhanced expression of sequences homologous to four of these, but in 12 out of 14 tumours Hayward *et al* found increased expression of RNA homologous to the oncogene of the acute leukaemia virus MC29 (an oncogene variously called *mac* or *myc*). The *myc*-specific RNA, which was not expressed above background levels in non-tumour tissue from

Structure and transcriptional products of the integrated ALV provirus

the same diseased birds, co-migrated with the same limited size classes of RNA that are detected in tumours with a probe for R-U5 viral sequences, suggesting that the *myc* sequences in the RNA were covalently linked to viral U5 sequences. This conclusion was strengthened by restriction enzyme digests of tumour DNA which showed that fragments containing proviral and flanking cell DNA were detectable with *myc*-specific probes, indicating that the provirus is integrated near the cell homologue of *myc* (*c-myc*). They concluded that in the bulk of ALV-induced lymphomas a viral LTR integrates near *c-myc*, enhances its expression, and this leads to neoplasia.

The data in favour of this promoter insertion mechanism of oncogenesis are attractive but there are a number of inconsistencies which must be clarified before this concept can be accepted. (1) In a minority of lymphomas there is no evidence for enhanced *c-myc* expression. (2) MC29 causes carcinomas and myelocytomas, not the B-cell lymphomas associated with ALV infection. In MC29 *myc* is expressed as a fusion protein, containing additional amino acid sequences encoded by a viral structural gene. Is this enough to explain the disparate pathogenesis? (3) Payne *et al*¹ and Cooper and Neiman (quoted in Hayward *et al*⁴) also find evidence for ALV insertion near *c-myc* but in some cases the provirus integrates downstream of the cell gene and it is not clear how the viral promoters directly determine *c-myc* expression (Payne *et al*¹ and P. Neiman, personal communication). The possibility of the virus acting as an insertional mutagen cannot be dismissed, particularly in view of the structural similarities between the integrated provirus and transposable genetic elements (discussed recently in *News and Views*⁵ and see Neiman *et al*⁶). (4) Cooper and Neiman recently showed that DNA from ALV-induced lymphomas

can transform recipient mouse cells⁷. This transforming DNA contains neither viral structural genes nor viral LTR regions and they have now shown (quoted in Hayward *et al*⁴) that the transforming DNA also lacks *c-myc* sequences.

Some resolution of these discrepancies can be attempted by postulating that *c-myc* functioning is needed for initiation but not for maintenance of lymphoid leukaemia. Provirus integration may stimulate *c-myc* expression (or perhaps maintain expression if the gene is already active) but this may serve simply to render the cells susceptible to further oncogenic change. A similar mechanism has been proposed for Burkitt's lymphoma in man, in which Epstein-Barr virus is thought to stimulate proliferation of B cells that are targets for additional neoplastic events, possibly involving chromosomal alteration. This view is supported by the natural history of avian leukaemia although lymphomas are not seen until four to six months after infection, ALV-induced nodules can be seen in the lymphoid organ, the bursa of Fabricius, within six weeks. The status of ALV and *c-myc* expression in these nodules has yet to be fully investigated. The nodules seem to be clonal, but only a subset of the cells they contain may progress to become metastatic lymphoma cells⁸. It is mainly these lymphoma cells that were studied by Payne, Neel, Hayward and co-workers^{1,2,4}, and the failure to detect either virus or *c-myc* expression in some of the cells, and in all transforming DNA⁷, may reflect tumour progression unrelated to the events initiated by ALV infection.

Whatever the role of *c-myc* in neoplasia, the finding that ALV infection is regularly accompanied by the expression of the cell homologue of a viral oncogene forges a link between mechanisms of oncogenesis by transforming and non-transforming retroviruses. The concept that cell genes can be neoplastic when controlled by a virus promoter has been seminal in recent investigations on the genetic changes that occur after chemical carcinogenesis (discussed in a recent *News and Views*⁹). The possibility that non-transforming retroviruses activate similar genes adds coherence to oncogene hypotheses of tumour formation and provides another refined system in which to investigate such ideas. ALV oncogenesis will clearly be studied in yet more detail and parallel investigations are doubtless being pursued with other retroviruses that do not carry their own oncogenes. □

Measuring atmospheric gases and aerosols

from Stuart A Penkett

APART from the formation of ions, there are two major photochemical processes which have been identified in the atmosphere. One results in the formation of a layer of ozone in the lower stratosphere and the other gives rise to a general oxidation process in the troposphere. The theory accounting for this second process, although put forward more than ten years ago¹, is not yet fully confirmed. It predicts that many chemical species such as hydrocarbons, halocarbons, sulphur and nitrogen compounds, are oxidized by hydroxyl radicals in the troposphere and converted to more soluble species which can be removed from the atmosphere by rain. This prevents many compounds, which are emitted both naturally and as pollutants, from reaching the stratosphere and interfering with the equilibrium of the ozone layer. The experiment entitled GAMETAG (Global Atmospheric Measurements on Tropospheric Aerosols and Gases) was an attempt by a group of American scientists to provide some evidence on the workings of this process. A series of twelve papers describing the work which took place in 1977 and 1978 has appeared in a recent issue of the *Journal of Geophysical Research*².

By the standards of atmospheric chemistry the experiment was a big one, based around the facilities provided by the National Center for Atmospheric Research at Boulder, Colorado (NCAR). It involved about forty scientists under the general guidance of Douglas Davis, C S Kiang, Paul Crutzen and Robert Duce and utilised a good proportion of the NCAR facilities for two years, collecting data over a flight track extending from Northern Alaska, down the North American continent and across the Pacific to New Zealand.

The most ambitious part of the experiment involved attempts to measure the hydroxyl radical concentrations both in the boundary layer and in the free troposphere above it. Hydroxyl radicals are formed by photolysis of ozone with light at wavelengths below 318 nm, which is about 30 nm above the minimum wavelength of solar radiation that penetrates the troposphere

The excited oxygen atom which is formed reacts with the large amounts of water vapour present to give rise to hydroxyl radicals

The concentration in clean air has been estimated to be about 5×10^5 molecules per cm^3 and various measurements in polluted air suggest a concentration range of 5×10^6 to 5×10^7 molecules per cm^3 (see refs 3,4). The best ground-based measurements have used a long pathlength UV absorption instrument which is not yet capable of measuring levels below 1×10^6 molecules per cm^3 . The fluorescence instrument used on GAMETAG was unlikely to improve on this, so although disappointing, it is perhaps not surprising that no data on the OH radical concentrations are presented.

Measurements were made on the global variation of the ozone and water vapour concentrations and of the photoproduction rate of singlet oxygen atoms, these enable the radical concentrations to be calculated by two-dimensional models of atmospheric chemistry which are currently being developed. In a world where measurements are not possible, calculations will have to suffice.

The radicals react with atmospheric trace gases such as methane in a complex chain reaction

The formaldehyde is photolysed to give carbon monoxide and hydrogen

and NO_2 is photolysed to give nitric oxide and oxygen atoms

The ozone which is formed in this way, and also ozone formed from CO oxidation, represents an alternative source to transport from the stratosphere⁵. The experiment showed that distinct ozone layers do exist in the troposphere, but in those observed over the ocean an inverse correlation between the ozone and water vapour concentrations indicated a stratospheric source. There was also no positive correlation between the ozone and carbon monoxide concentrations. The reason is almost certainly lack of sufficient nitric oxide to sustain the chain reaction. Recent measurements⁶ over the Pacific Ocean confirm this and the conclusion

must be that the extent of the atmospheric oxidation process over the ocean is very limited and far from producing ozone, photochemical reactions act as a sink.

Measurements of sulphur and halogen gases and many aerosol components both in and above the atmospheric boundary layer were also made. The sulphur measurements were particularly interesting since they suggest that sulphur dioxide is formed in the free troposphere above the boundary layer. There is also evidence that much of the sulphate aerosol observed was formed by a gas to particle conversion process occurring within the atmosphere. Atmospheric sulphur chemistry has been a subject of discussion for three decades and more. Much of this has focused on the natural sources of sulphur, whether they are present as hydrogen sulphide or dimethyl sulphide. Recently two more gases, carbonyl sulphide and carbon disulphide, have been shown to be present in the atmosphere⁷ and it has been suggested that these are the main precursors of sulphur dioxide and the sulphate aerosol found in the remote troposphere⁸. The GAMETAG experiment has certainly proved beyond doubt that carbonyl sulphide is the most abundant sulphur-containing trace gas in the atmosphere. However, it is not clear yet how quickly it is oxidized^{9,10}.

GAMETAG showed very little evidence for the presence of long-range transport of pollutants from the continents over the ocean. This was true of gases such as carbon monoxide and sulphur dioxide and for aerosol species such as sulphate and nitrate. It is also clear that the ocean is the major source of methyl chloride, which is the only naturally produced halogen-containing gas to enter the stratosphere in large quantities.

In conclusion, GAMETAG provided some interesting data on the concentration distribution of stable trace gases and aerosols and the influence of pollutants on the composition of the remote troposphere. However, it failed to provide positive evidence for the existence of a large amount of chemical activity in the troposphere. Most probably this is associated with low levels of nitric oxide over the oceans, which suppresses the level of hydroxyl radicals.

The continents are likely to be the major source of nitrogen oxides and these are the places to look for evidence of atmospheric reactions. There is certainly a case for an experiment of this type to continue if only to confirm that many compounds released from modern industry are destroyed before they can reach the ozone layer in the

stratosphere. It should concentrate on unpolluted continents in tropical latitudes and it should include measurements of transient products such as aldehydes and nitro compounds. These are easier to measure than radicals but provide the sort of information which is necessary to test theories of atmospheric oxidation. □

Cracks in rocks under stress

from Barry Atkinson

MICROCRACKS influence many of the physical properties of rocks. Strength, transport, elastic and inelastic characteristics are all highly dependent upon the size, shape, number and distribution of microcracks. These physical properties change dramatically as crack characteristics are modified under stress.

In earthquake prediction, the exploitation of oil, gas and water bearing formations, nuclear waste disposal, and heat extraction and storage, the prediction of *in-situ* physical properties from models of rock microcracks is of great importance but has, so far, been rather unsuccessful. The basic problem is that, despite many laboratory studies, we have only a rudimentary idea of the actual modifications that cracks undergo in stressed rocks. M. L. Batzle, G. Simmons and R. W. Siegfried of MIT have recently attempted to overcome this problem by making direct observations of crack closure in granite and diabase under uniaxial compressive stress (*J geophys Res* **85**; 7072, 1980).

The MIT group placed a small hydraulic press inside a conventional scanning electron microscope (SEM) so that they could subject cylinders about one cm in diameter and two cm long to uniaxial stresses of up to 30 MPa. A portion of the lateral side of the core was ground flat and bombarded with ionized argon to remove the damaged surface before examination in the SEM. Stress-strain measurements were also made on similar cores in the press but outside of the SEM. Although SEM studies have been made before on specimens subjected to tensile *in situ* stresses, this is the first time that a compressive stress has been so studied.

Westerley granite and Maryland diabase were examined in the 'natural' state and after slowly heat cycling to 500°C and 700°C, respectively, to increase crack porosity. Westerley granite is a typical crystalline rock with initial crack porosity of about 0.2 per cent and a total porosity of about 1 per cent. Maryland diabase is unusual in that it has no measureable crack porosity and a low total porosity of 0.1 per cent. Westerley granite consists of roughly equidimensional feldspar, quartz and

biotite mica grains averaging 800 micrometres in diameter. Maryland diabase consists mainly of equidimensional grains of feldspar and pyroxene averaging 200 micrometres in diameter.

In general, the response of cracks to stress confirmed those predicted from microscopic examinations made at zero stress (Kranz, R. L. *Int J Rock Mech Mining Sci Geomech Abstr* **16**; 37, 1979) and from deformation measurements made under applied stress (Brace, W. F. *et al J geophys Res* **71**, 3939, 1966). Numerous factors influence the behaviour of cracks, including orientation, shape, source, and the proximity of other fractures.

The main conclusion of the recent work, however, is that pre-existing cracks in these rocks behave quite differently to those induced by heat cycling. Pre-existing cracks have walls that are irregular, etched and pitted, and poorly matched. Under stress, closure is incomplete with many portions remaining open and interconnected. The shape, or aspect ratio, continually changes as stress increases. Thermally induced cracks are also irregular but the walls are more perfectly matched and tend to close more completely, unless propped open by very small grains or debris.

Although pre-existing fractures can be re-opened, widened, extended, or closed, depending on a host of interrelated factors, in general those cracks oriented close to the direction of maximum stress tend to open, whereas those oriented nearly perpendicular to the maximum stress tend to close.

New cracks created in the laboratory by stress or temperature usually have the irregular but well matched characteristics of thermal fractures. This is important because the precise nature of the crack response to stress determines the trends in dependent physical properties. New fractures will close easily and hence lead to a large change in physical properties with stress as compared with the more inefficient

closing of pre-existing cracks.

How then do induced cracks attain the characteristics of pre-existing cracks? A key element in this seems to be the extent to which cracks are modified by the circulation of water at high temperatures. Under these conditions grains become rounded and crack walls etched and pitted (Potter, J. M. *Rep LA-7224-T*, Los Alamos Sci. Lab., 1978) and begin to resemble pre-existing cracks.

The fact that almost complete closure of thermal and stress-induced cracks can occur lends support to D. J. Holcomb and J. L. Stevens' assertion that reversible Griffith cracks can explain all of the observed attributes of rock dilatancy (*J geophys Res* **85**; 7101, 1980). They cast doubt on the widely used sliding crack model of dilatancy, in which dilatancy arises from the formation of tensile cracks at the ends of a large number of sliding shear cracks, partly because a shear crack model cannot explain the stress memory rocks exhibit and especially because shear cracks are only rarely observed in some dilatant rocks (Tapponier, D. and Brace, W. F. *Int J Rock Mech Mining Sci Geomech Abstr* **13**; 1976). On the other hand, long, narrow cracks preferentially oriented parallel to the maximum compressive stress are very common in some rocks and these Griffith cracks can apparently explain all of the experimental results on rock dilatancy, provided that the cracks can open and close reversibly under stress.

A problem arises, however, because most studies of stressed cracks in rocks have been made on low-porosity, well-cemented crystalline rocks. Less well-cemented, high-porosity sedimentary rocks with more point contacts and fewer interlocking grains have quite different initial preferred orientations and distribution of microcracks. Recent experimental studies have shown that the differences in peak strength, the localization of deformation to give a main fault, and some water-weakening effects can be qualitatively explained in terms of the initial microstructure (Hadizadeh, J., Thesis, University of London, 1980).

Two limitations of the MIT study are that we are not sure their observations are typical of the bulk of their specimens. They examined sections that were within 1 mm of the surface, and the role of stress corrosion crack growth was not investigated in the high-vacuum environment of the SEM. *In-situ* tensile tests, however, show that stress corrosion can be a significant factor (Swan, G. *Res Rep*, Tulea 1980 01, University of Lulea).

It would now be valuable to extend *in-situ* observations to higher stresses and temperatures and more complex polyaxial stress states. At present this is not possible and one is forced to examine at zero stress and ambient conditions specimens that have been retrieved from more exotic conditions. □

SPRING BOOKS SUPPLEMENT

Reviewers without pride or prejudice

What are book reviews for? The question is not entirely trivial. The pages that follow are filled with the comments of a great many serious people who have taken the trouble to read some book or books, to reflect on the contents thereof and then to tell the rest of the world what they think of them. Why, it will be asked, should they bother? Why should an army of people who are (or who should be) disinterested take this trouble for the sake of others — the people who lie somewhere between those who would certainly buy the book concerned, perhaps because it represents a special interest of theirs, and those who would not willingly be seen in public reading the document concerned, and who would not wish to do so in private either? Pecuniary reward is not the explanation. The simple answer is that book reviewers pursue one of the most honourable of intellectual crafts. The ideal reviewer is a self-effacing person — the kind of person who is sufficiently knowledgeable to have written the book he is charged with off his own bat, who might well indeed have done so if he were not so busy, but who has nevertheless been willing to quarry time from a busy timetable to inform and instruct potential readers of a new apparition in the literature. The scientific community, any intellectual community, has reason to be grateful to reviewers.

But why are books so especially deserving of attention? What is it about a pair of hard covers that gives a book precedence over, say, an article in a scientific or other journal? Rarity is only part of the explanation. Some journals, *Nature* among them, do indeed try to pick out and draw to the attention of their readers particularly interesting articles that appear in the ordinary course of communication. The volume of the scientific literature is of course too great for this task to be attempted (or at least accomplished) systematically. There is, however, another sense in which a book commands (and deserves) to be dealt with differently from the report of some piece of research, whatever the excitement engendered by the results. For a book, or at least a good book, is necessarily a somewhat personal declaration. So much can be told from a comparison of the style of run-of-the-mill scientific articles and books by the same authors. The authors of articles run to the passive, and to opening sentences such as "There is now much evidence to suggest that ...". The authors of books write in a different frame of mind. They are, from time to time, prepared to utter sentences beginning "I believe that ...". More than this, books differ from articles in the journals in their objectives. Both kinds of contributions to the literature have a beginning and a middle, but only of books (or good books) is it required that there should also be a conclusion of some weight and finality. The authors of articles in the journals are allowed to finish with a statement to the effect that they are entirely at a loss to understand the observations they report and to declare that they will do their best, in competition with those who are stimulated by reading their contribution to the literature, to find out. Would-be book authors, by contrast, must (or should) know before they put pen to paper what case they seek to make. (Publishers who make books by stringing together a miscellaneous collection of articles, or collections of papers given at some symposium, must by the same token appreciate that these are comparatively dull, not much like books.)

There is another crucial respect in which a book differs from some other contribution to the literature. Although some books may only be ten times longer than, say, some journal articles, the

difference of scale is a quantitative difference big enough to imply a qualitative difference. As the world knows, book authors are repeatedly perplexed to know whether the point they are about to make in chapter umpteen has already been made in chapter one. Put simply, those who set out to write books, and actually finish them, command a certain respect, even from those who may disagree with the conclusions.

Good reviewers appreciate these truths, and are (or should be) compassionate people. If somebody writes a routine account of, say, the inorganic chemistry of selenium, and if the arrangement of the chapters is not precisely what the reviewer would have chosen, that does not amount to an excuse for a fierce attack on the author and his good sense and a warning that students everywhere should avoid the book like the plague. In such fields it is well known that the unkindest course a reviewer can follow is to say nothing at all: then potential purchasers will have to learn of the book by chance, while the book's publishers will be at their wits' end, seeking other ways of putting news of the book's appearance into circulation. In the last resort, after all, the reviewer's task is to tell potential readers what a book seeks to accomplish and to say whether the author has done what he set out to do. Part of the book reviewer's licence is that he may, in passing, add a few reflections of his own on the good sense of the author's goal. So most book reviews should be essays in sympathetic understanding, marked sometimes with sorrow, rarely with anger. And so they usually are.

There are, however, exceptions to this benign rule. For the class of well-conceived books, each with its own sharp conclusion, is bound to include many whose conclusions are at once mistaken, even mischievous, but also likely to be persuasive. This is why the craft of book reviewing frequently runs to polemic. This is why H. J. Eysenck's *The Causes and Effects of Smoking* (Temple Smith, 1980), or Samuel Epstein's *The Politics of Cancer* (see *Nature* 284, 297, 1980) persuaded reviewers to soak their typewriter ribbons in vitriol. The arguments, right or wrong (and probably wrong, or at least incomplete), are such a challenge to accepted doctrine and at the same time so self-consciously challenging that it is helpful to readers to know the strength of opinion on the other side. Polemic is therefore part (but ideally a small part) of book review columns. Professor Dorothy Hodgkin's review of Maurice Goldsmith's book on J. D. Bernal (*Sage, Hutchinson*, 1980, see *Nature* 289, 99, 1981) is more puzzling. Goldsmith set out to write a biography of one of his heroes, and was savaged for his pains by another hero-worshipper, his reviewer. No doubt the book is, as Professor Hodgkin says, "confused and inaccurate". It is also, however, a good book in the sense of being a good read and also (for a hero-worshipper) honest in that it deals with the warts as well as the achievements — sexual proclivities, ambivalence about Lysenko and all that. Maybe Goldsmith's book is "not the book that is needed about Bernal", but it is the only book we have. On this occasion, polemic seems to have been misplaced. In general, the truth about books is that they are milestones for somebody — certainly the author and the publisher — and that there are some occasions on which even bad books are better than no books. Moreover, books differ from other contributions to the literature of scholarship in the diversity of their readership. Their influence on students is important. And books — or good books — can survive from one decade to another.

Advice and dissent in White House science

Harvey Brooks

THE growing literature of science policy generally includes two kinds of books: first-hand accounts of their own experience by principal actors in the processes of high-level scientific decision-making, such as those by James Killian, George B. Kistiakowsky and Herbert York, or analytical discussions by academic scholars based on study of official documents or interviews with the principal actors. Edward Burger attempts to build a bridge between these two genres. A member of the staff of the Office of Science and Technology (OST) from the time of the first Nixon administration to the abolition of the President's Science Advisory Committee (PSAC) and OST in 1973, Dr Burger has built his book firmly on his own first-hand experience as an insider, but at the same time has attempted to bring a historical and analytical perspective to this experience and to put forth some important generalizations.

To the average observer of science policy, the Nixon administration tends to be viewed as the low point in the history of science in the White House. The rather sudden decision to abolish the presidential science advisory apparatus in January 1973 overshadows the many constructive initiatives that arose during this period. As Burger reminds us, this was a time when the effort to "civilianize" OST and PSAC — to bring scientific considerations and the potential of science fully to bear on some of the nation's major sociopolitical issues such as health care, environmental regulation, population policy and urban policy — reached its climax.

His account is notable for its political sophistication and sensitivity to the multiplicity of influences bearing on even the apparently scientific decisions. It is also refreshingly free of self-justification or overstatement of the role of science. The chapters on national health policy, on environment and health, and regulation to protect health and on population and family planning contain a wealth of new material relating to major Nixon administration initiatives in social policy which gradually became diluted by pluralistic political pressures. These chapters are well worth reading even by those who care little about science policy or the role of science in the White House.

The subtitle of the book is unfortunately somewhat ambiguous and fails to do justice to all the themes which Burger develops. Its meaning is never fully explained and conveys implications that are not really supported by Burger's detailed conclusions. It is thus not clear whether he means to imply that having a Science Advisor in the White House is a

Science at the White House: A Political Liability By Edward J. Burger Jr. Pp 208. ISBN 0-8018-2433-8 (Johns Hopkins University Press 1980) \$14.95, £9.

political liability to the President, which tends to tie his hands in negotiating with the many contending constituencies that he has to satisfy or whether having a prominent presence in the White House is a political liability for the scientific community which compromises its long-term credibility before the public. Perhaps both statements are true, but I do not believe that the implication that science should be taken out of the White House is either intended by Burger or justified by the case histories which he analyses so perceptively.

In fact one could argue that science in the White House enjoyed some of its finest hours during the period covered by this account, if retaining the intellectual honesty of science in the policy process is used as a criterion. The report on *Chemicals and Health*, published by the National Science Foundation after the demise of PSAC, is still one of the most thorough and balanced discussions of this controversial topic. Issued in a climate of overwhelming environmental activism, its sober and balanced approach was little appreciated or heeded until much later. Had it been heeded, some of the current over-reaction against the earlier excesses of the environmental movement might have been avoided. The Toxic Substances Control Act (1976) derived from a concept that originated from the staff of the Science Advisor. The OST staff, and Burger in particular, played a central role in shaping the recommendations of the Health Policy Review Group (1971) and the subsequent Presidential Message on Health. The analysis of the Review Group stands up very well today, though it had little political effect at the time. The OST also played an important role in following up the report of the Population Commission (1972), although here again the analysis was ahead of its time in political terms. The Science Advisor played a reluctant but sensible role in devising the Quality of Life Review Process for considering the social and economic impacts of regulatory decisions, anticipating the regulatory review process established in the Carter administration. The Science Advisor chaired a special committee created by the President to study the rather grandiose and politically motivated proposal for a New Technology Opportunity Program in 1971.

The recitation of these examples, however, poses the dilemma suggested in the title of the book. In referring to these

activities favourably I am making an intellectual — not a political — judgement, because in most instances the input from the OST, as Burger suggests, must be rated a political failure. The intellectual conclusions were mostly out of tune with the political climate and the President's political goals — the classic problem of "speaking truth to power". The report on *Chemicals and Health* took too long to complete and appeared too late to have any significant impact on policy, and its balanced approach was out of tune with the public's mood. By the time the hard hitting and clever recommendations of the Health Policy Review Group had been distilled into a presidential message, much of the bite had disappeared, and health as a salient political issue had faded into the background. Much the same fate befell the report of the Population Commission. The task force to follow up the report completed its work at a time when political concern over US population growth had faded with the dramatic decline in fertility in the early 1970s. Although the task force called for a presidential statement to endorse the Commission's principal recommendation for a national population stabilization policy, the chairman privately sabotaged this recommendation. The technology initiatives programme, which was launched with great political fanfare, quietly foundered when Dr Edward David's standing committee discovered there was much less there than met the eye, and was unable to identify any dramatic government initiatives that stood up to scientific scrutiny.

We thus end with a picture in which strong recommendations based on scientific input failed politically because they ran counter to the prevailing climate or antagonized strong political interests, on the one hand, or in which careful analysis debunked political initiatives on which the President had set great store, on the other. Are the Science Advisor and his staff to be praised for "speaking the truth to power", for calling the shots as they saw them and for thoughtful and forward-looking policy analysis? Or are they to be criticized for insufficient awareness of political realities and of the sensitivities of important political constituencies to which the President must respond? Is the performance of science in the Nixon White House to be viewed as a series of honourable failures derived from commendable devotion to intellectual honesty and objectivity? Or is it to be condemned as the mark of politically naive amateurs incapable of appreciating and responding to the legitimate political needs of the chief executive? Burger poses these

Scientists at the White House, 1957–1981. Left to right, top to bottom: James Killian Jr (served under Truman, 1957–1959); George Kistiakowsky (Eisenhower, 1959–1961); Jerome Wiesner (Kennedy, 1961–1964); Donald Hornig (Johnson, 1964–1969); Lee Du Bridge (Nixon, 1969–1970); Edward David Jr (Nixon, 1970 to 1973 when PSAC and OST were abolished); H. Guyford Stever (Ford, 1976–1977); Frank Press (Carter, 1977–1981). President Reagan has not yet appointed a successor to Press.

questions cogently in each of the examples which he analyses, but he does not really give us the answer. Perhaps there is no single answer and the greatest contribution of the book is revealing the dilemma in realistic detail.

An important theme of this book, set forth in Chapter 2, is the fundamental conflict between rational policy planning and the push and pull of pluralistic political interests. The author presents the executive branch and the scientists as the proponents of such rationality against the pluralism embodied in the legislature. Yet there is a paradox here, which is not fully resolved in the book. It is true that in the efforts to introduce Program Policy Budgeting (PPB), to develop a comprehensive health policy or to formulate a rational and balanced national policy for environmental regulation, Burger's model seems to apply. But he fails to note that in policy for science, as contrasted with science for policy, the roles of the scientists and politicians appear to be reversed. It is Congress that has continually pushed for a comprehensive national policy for science, most notably in the National Science and Technology Policy, Organization and Priorities Act of 1976. Furthermore, this is

not a new phenomenon. In the nineteenth century, Congress was the repeated source of proposals for a cabinet Department of Science. In every case it has been the scientific community and the executive branch that have dragged their feet in regard to the comprehensive planning of science and technology. More recently, OSTP under the Carter administration has attempted to divest itself of most of the planning and systematic reporting functions mandated by the 1976 Act. Whereas Congress has viewed OSTP and the Science Advisor as a kind of general staff for science and technology in the United States, the Science Advisor and most of his constituency in the technical community have viewed his role more modestly and have strongly favoured a pluralistic, decentralized approach to the support of science itself.

It is interesting to speculate on the causes of this paradox of science as the advocate of planning in the spheres of public policy and pluralism in the field of science, while the Congress and the more politically minded Executive take the exactly opposite view. The answer may lie in the internal politics of the scientific community itself. This community is not a monolithic group

but rather congeries of frequently conflicting interests and views. Planning for science, especially by scientists, entails a high political cost within the scientific community, which would rather take its chances on the free play of political advocacy between the different segments of the scientific community and the political process. It would have been desirable if Dr Burger had explained this particular paradox a little further.

Altogether, though, this is a valuable book which should be of interest to a wide public. It provides some fascinating insights into some of the major social policy debates of the early 1970s; it is a contribution to the analysis of the role of White House science advice from the perspective of a staff officer carrying out policy support rather than making policy; and it provides excellent case material for scholars and students in the field of science policy. On top of that it is well written, literate and sophisticated. □

Education and the compleat scientist

J. Z. Young

Teaching and Learning about Science and Society. By John Ziman. Pp.190. ISBN 0-5212-3221-X. (Cambridge University Press: 1980.) £9.50, \$22.50.

MOST scientists are interested in scientific education, if only for the memory of their own debt to it. I imagine that a great many became scientists because they were lucky enough to have an inspiring teacher. My own at Marlborough College was A. G. Lowndes, a remarkable man who trained several Fellows of the Royal Society and a Nobel Prize Winner (Peter Medawar). He inspired us by his own somewhat amateur researches, he showed us endless living things and, by making us work even in our spare time, taught us that all science involves much hard work.

These are perhaps the main items that must be included in any scientific education: it must catch enthusiasm, it must cover a huge mass of facts and it must find out those who can enjoy learning a lot of detail. This is how scientists are made, but in the process they seldom learn much about the position of science in society, still less about its history or philosophy.

It is these defects that are the particular concern of Professor Ziman as indicated by the title of his book. I cannot remember ever hearing them discussed by my teachers either at school or university. Probably many scientists still take up their subject because they are interested and like it, though there is now more concern about its social implications. They are all too liable to fall into what Ziman calls "scientism and technocracy", the uninformed assumption that everything that is done in the name of science is good. How can this restriction of the development of young scientists be avoided? Ziman has tried to encapsulate the problem under the acronym STS — Science, Technology and Society. These themes permeate the political, economic and cultural issues of our times yet "there is no *rationale* of STS as an educational subject", although various courses of study of it have been tried. In trying to provide this rationale Ziman manages to stimulate thoughts about a great many fundamental questions, even beyond those dealing with the educational problem itself.

For instance, one feels that the discussion obviously needs a definition of science, and many times Ziman seems on the point of providing one, but wisely never comes down to calling it a definition. Sometimes it is a question of method: "Science derives its practical power and authority from the rigours of its arguments and the hardness of its facts". Moreover, he repeatedly stresses that the production of scientific knowledge is a social process. Then only a page later we are in a different world of discourse: "There is no single

'scientific' map of reality — or if there were, it would be much too complicated and unwieldy to be grasped or used by anyone". Is this true? I suspect that Ziman doubts it himself. He pursues the question into a discussion of the hierarchy of scientific enquiry and the questions of emergence and reductionism,

the notion that the properties of complex systems such as organisms or molecules can be 'reduced' to the laws satisfied by simpler systems such as cells or atoms — is not only a very dubious philosophy, it is a dangerous folly in science education, where the map appropriate to each level must be taught wholeheartedly according to its own lights

Yet probably most scientists have a hankering for that "folly". And is it indeed so foolish? It is true that chemistry and biology have their own laws but no one can go all the way in either of those sciences unless they know something about physics. However much "autonomy" there may be for each part of science there is still, at least for many of us, a scientific map or model of the world to which we try to refer all events and all knowledge, including the knowledge of ourselves. It seems that the human brain is so constructed that it tries to build all its information and schemes of action around a unified model. Of course this grows gradually in each one of us, centred at first around a parental scheme. The scientific model, if properly learned, can provide the adult substitute, which many people feel they lack in the absence of religion. That is of course not to say that science should be dogmatic or be treated as religion, but that it can provide what Ziman calls "the possibility of discovering order in nature" and to do this is a requirement for human life. We all need some system of order. Incidentally this is a characteristic specific to human beings and not present in our nearest relatives. Ziman actually recognizes this later in his book

when he says that "scientific world pictures" allow "deductions that help us along the way through life".

This is only one of the ends that he believes could be achieved by the proper attention to STS education. He holds that they can only be reached by specifically designed courses for all levels of scientific education. In the later part of his book he discusses how these should be planned for different stages. He is against "General Science that is too sloppy and technical science that is too arbitrary", and he advocates a "valid science". This is easy enough to say until you come to the job of deciding what to put in and what to leave out. Ziman discusses the many ways in which it could be done. For instance, it can be through the social relevance and applications of science, through its possibilities as a vocation for the individual, or its history, or its philosophy or its value in solving world problems. But he does not try to specify the content of particular courses. His aim is to show that the teaching of science at present is grossly defective because it does not properly develop the understanding of the individual either of himself or society, or indeed of the nature of the science he is learning. His plea is that teachers of science should take definite steps to fill this gap by designing what he calls STS courses. He knows that there will be much opposition and anyone who has tried to introduce such courses will have experienced this. But there are many people ready to agree with his plea that a better understanding of the relations of science and society is needed for the proper training of research scientists as well as doctors and other technologists, not to mention civil servants, politicians and the general public. A major value of this interesting book is that it makes you realize how difficult it is to reach agreement either about the nature of science or its proper place in society. □

IQ gladiators in separate combat

Stuart Sutherland

Intelligence: The Battle for the Mind. H.J. Eysenck versus Leon Kamin. Pp.192. ISBN hbk 0-333-31279-1/0-471-08884-6; ISBN pbk 0-330-36399-4. (Macmillan Press, London/Wiley, New York/Pan: 1981.) Hbk £12, \$12.95; pbk £2.95.

NATIVISTS have battled with empiricists for many years, but never with such fury as over the inheritability of intelligence. It might be thought that the issue could be resolved by bringing together representatives of the opposing sides and letting them argue out, point by point, the

evidence for the respective roles of inheritance and of environment. *Intelligence: The Battle for the Mind* could have provided just such an opportunity, but unfortunately it is constructed in such a way that the combatants only skirmish and never meet in a decisive battle.

The book contains four sections. In the first, Professor Eysenck sets out his case for supposing that in Western society inheritance accounts for about 80% of the variation in intelligence. Although he does not enumerate them, he deploys 20 different lines of evidence from which he claims this inference can be drawn. In the second

section, Professor Kamin produces his criticisms of some of the evidence for the importance of heredity, but this section is not a reply to Eysenck's initial foray since it was evidently written without Kamin having read it. In consequence, many of Kamin's arguments are beside the point: for example, although Eysenck excludes all reference to Burt's data, now universally acknowledged — thanks to Kamin's brilliant detective work — to have been faked, Kamin devotes a chapter to attacking Burt. In the final two sections, which are much too brief, Eysenck replies to Kamin's set-piece and Kamin to Eysenck's, and there the matter rests.

No agreement is reached on which aspects of the evidence are reliable and which are not, and both authors are guilty of failing to meet the arguments adduced by the other. Thus, in his opening section Eysenck ignores many of the criticisms previously levelled by Kamin. For example, one of the strongest arguments in favour of the role of inheritance is that when monozygotic twins are brought in by foster parents, there is a higher correlation between the IQ of the natural parents and the child than between that of the foster parents and the child. Kamin has put forward two ingenious suggestions to explain this correlation in environmental terms. First, many of the foster children in question spent a year or more of their lives with their natural parents before moving to foster parents. Second, the IQ and the socio-economic status of foster parents is in general high and has much less variance than the IQ of the population at large: this reduction in environmental variance would reduce the effects of environment. One would have liked to have seen Professor Eysenck's reply to these arguments, but it is not to be found in the book. On the other hand, Eysenck points out that there is a higher correlation between the IQs of monozygotic twins reared together, but one looks in vain for Kamin's response to this argument.

Both authors give the impression of being determined to make a case and of selecting data that forward that case. It is a pity that Eysenck did not concentrate on the most solid evidence for inheritability and ignore dubious or unrepeatable findings. For example, he argues that there is a difference in the brain waves (EEGs) of the intelligent and unintelligent and that this difference suggests intelligence is inherited. Not only is the argument fallacious, since there is no reason why brain waves should not be in part determined by environmental factors, but recent attempts to repeat the finding Eysenck uses have failed.

Eysenck points out that Kamin does not have a theory of intelligence. With great ingenuity, Kamin has taken a number of pieces of evidence thought to support the hereditary case and has shown that there are other *possible* explanations: he has not proved that these other explanations are

correct. Moreover, since Kamin treats each piece of evidence in isolation, he is able to use individual arguments that are inconsistent with one another. Thus, as Eysenck notes, Kamin explains the large differences in IQ between dizygotic twins reared *together* by assuming a large difference in the way they are treated within the family. Elsewhere, however, he explains the similarity in the IQs of monozygotic twins brought up *apart* by arguing that each pair is placed in families of a similar socio-economic background. Taken together, Kamin's two arguments imply the absurd conclusion that there is less environmental difference *between* families than *within* a family.

There are a few things on which both authors agree. Moving children from deprived homes to particularly good homes can bring about a shift of up to 20 points in IQ. Although Kamin regards this as compelling evidence for the overriding importance of environment, Eysenck is able to show that it is consistent with his own theory of intelligence. He does not maintain that a large shift in environment cannot change IQ, merely that in conditions as they exist today IQ is more determined by heredity than environment.

Kamin does not help his case by his personal virulence towards Eysenck. The fact that Eysenck has twice made a mistake about the sex of an author whom he cites has surely nothing to do with the inheritance of IQ; and it is merely distracting to the reader for Kamin to stress past errors made by Eysenck, at least some of which (for example, his defence of Burt) Eysenck now acknowledges. Moreover, Kamin's allegation that the aim of the science of genetics is to make "the world comfortably safe for white males" is both vituperative and false — white males were a good deal safer before IQ tests were ever thought of. Eysenck rightly insists that differences in the average IQs of groups have no bearing on how the individual should be treated. It is impossible to predict the individual's IQ from skin colour, sex or social class and in at least some instances the use of objective tests for selection has favoured underprivileged groups. Burt may have been a scientific scoundrel, but his introduction of intelligence tests for secondary education in Britain between the wars doubled the proportion of poor children in secondary schools.

Like all scientific discoveries, the results of work on intelligence testing can be used for good or ill. As Eysenck notes, recent decisions by anti-racists in the United States are likely to be extremely damaging to minority groups. For example, it is folly to insist that equal proportions of blacks and whites should enter training programmes for the educationally subnormal, if, for whatever reason, a higher proportion of blacks than of whites need the help of such training. Eysenck quotes a remark of Dr Johnson's which sums up the position: when asked whether

men or women were more intelligent, he replied: "Which man? Which woman?"

Intelligence: The Battle for the Mind is a wasted opportunity. One feels that had Eysenck concentrated on the most compelling arguments for the role of inheritance, and had he attempted from the outset to meet Kamin's ingenious but *ad hoc* arguments where they could be met and conceded cases where they could not be met, the debate might have been settled. Eysenck might not have proven that IQ is 80% inherited, but he might have established once and for all that there is a strong inherited component.

Neither combatant comments on the scientific importance of intelligence testing. A much more destructive criticism can be made of the whole enterprise than any advanced by Kamin, namely, that it has told us nothing about how the human mind works nor has it given any answer to the really important applied problem — how can we make it work better? □

Stuart Sutherland is Director of the Centre for Research on Perception and Cognition at the University of Sussex.

Reality of science

Peter Newmark

An Imagined World. By June Goodfield. Pp.288. ISBN 0-06-011641-2. (Harper & Row: 1981.) \$12.95 US only.

IF A scientist wishes to discover what makes a certain type of cell tick, she may well spend five years studying its behaviour and composition. If a writer wishes to find out what makes that scientist not only tick but chime, by way of making scientific discoveries, she may decide to track the scientist's every thought throughout the five years. That neither venture is guaranteed to succeed is illustrated by this book. The story, however, is not without interest.

In 1975 June Goodfield met Anna Brito (a pseudonym) who was then on sabbatical in New York and, within hours, decided that she fitted the bill of an individual research worker through whom to follow the process of science. Goodfield found Anna Brito "articulate, amusing and somewhat different from the majority of scientists I had met before", and sensed that Brito was at a stage where doors were beginning to open. In one sense, at least, she was right. Within a year of returning from New York to Glasgow University, the doors of New York's Memorial Sloan-Kettering Cancer Center had opened to Anna Brito. From then on Goodfield had ready access to the scientist. So except for the first year and for a period in 1977, when progress is recounted through letters and tape recordings, the tale is told in narrative form.

Through the letters, recordings and narrative emerges a story that illuminates the working life of a scientist in a detailed and open way that has seldom, if ever, been done before. Unlike *The Double Helix*, *An Imagined World* contains little glamour, much toil, many failures, much anguish and no prizes. It is, in a word, realistic. Whether that makes for interesting reading is a matter of taste. Certainly for the working scientist there will be few surprises, but there may be reflections, both pleasant and not so pleasant, to be seen in the mirror of Anna Brito's progress. For the non-scientist who does not realize just how great a travesty of the making of a discovery is the usual account given in a scientific paper, the book is bound to come as an eye-opener.

It would be hard, however, to claim that Anna Brito's experiences were particularly typical. Her first, and arguably most important, discovery certainly came about in an unusual way. She found herself in a London laboratory, unable to speak much English, having neither skills nor ideas to offer and altogether a rather unwanted visitor. Her supervisor, somewhat in desperation, gave her a large collection of sections of mice to examine through a microscope. Against all the odds she noticed something both original and interesting. Her observation amounted to the discovery that T-lymphocytes and B-lymphocytes have predilections for separate zones of tissues.

In the years that followed, Anna Brito pursued her discovery of what she called "ecotaxis" and developed the idea that certain diseases were associated with wrongly located lymphocytes. This condition she called "ecotaxopathy", a term guaranteed to turn purple the faces of many immunologists. Clearly not a lady to be thrown off course by such reactions or by what, to many, would surely be an unnerving number of grant refusals, her research continued in the same vein throughout the period covered in the book.

Much of what is recounted rings true; for example, the long periods Anna Brito spends reading around her subject hoping to place her observations into a broader context. Other features of her laboratory life seem less convincingly told. Only twice, for example, is there any mention of her having any scientific competitors. This is either true and untypical, or untrue and misleading, given the extent to which competition drives so many scientists.

The chief virtue of the book is that it recounts in detail the thoughts and actions of a scientist brave enough to be open about her mistakes and failures and to bare many of her thoughts, despite the risk that some might look naive at the time and worse in retrospect. But the book fails to shed much light on the process of scientific discovery or to sustain interest for one simple reason; as it happens, nothing that I could classify as a substantial discovery emerges during the period covered in the

book.

Finally, potential readers might be attracted by two puzzles. The first, not too taxing, is the real identity of Anna Brito. The second, perplexing, is why, given the circumstances of the initial discovery that set her on the pilgrimage of research, Brito

can later say: "I can't stand people who just put everything together and try to see what happens — who don't think before doing an experiment . . . I could never do science like that"?

Peter Newmark is Deputy Editor of Nature.

Will the real Beaker Folk please stand up?

Colin Burgess

The Beaker Folk: Copper Age Archaeology in Western Europe. By Richard J. Harrison. Pp.176. ISBN 0-500-02098-1. (Thames & Hudson: 1981.) £12, \$19.95.

"BEAKER Folk", like the Wee Folk, exist in the mind of the beholder, and Dr Harrison is as uncertain in his attitude to "Beaker Folk" as most of us are about fairies. His last chapter, "Was there a 'Beaker Folk'?", was eminently sensible, and his conclusion that they "have no substance as a special population group", and that the Bell Beaker phenomenon began "as a fashion in fine pottery", would meet with widespread approval among students of the subject.

Gorge of the River Verdon in Provence, "an exceptionally interesting site".

Unfortunately, this attitude does not square with the contradictions in his preceding six chapters. The author claims in several places not to believe in "Beaker Folk", but clearly finds it difficult to erase them from his subconscious. His inner confusion will leave the reader feeling profoundly uncomfortable, because it is obtrusive throughout: to quote from the jacket, "the so-called 'Beaker Folk' were not a separate, well-defined community, but constituted more of an influence or movement", yet in the next sentence "They appear to have been instrumental in introducing metal technology", and their arrival "coincided with major changes in the structure of primitive society". Such ambivalence left me wondering at the end whether the author had experienced a late

change of heart about "Beaker Folk", and been forced to take a scalpel to his text; or perhaps it is simply that he, like most of us, finds it difficult to adjust to a world without "Beaker Folk".

In many ways, Harrison engineers his own downfall. On p.13 he complains that "One bad habit which many archaeologists have had is to abstract beakers from their local settings and study them as something alien and isolated", which is exactly what has bedevilled study of this period in Europe, and is exactly the mistake this book perpetuates. For sadly, Harrison is largely concerned with his title, *The Beaker Folk*, and hardly at all with his subtitle, *Copper Age Archaeology in Europe*. But until the former is strictly subordinated to the latter, understanding of this exciting phase of European prehistory will advance very little.

There is a fundamental controversy about Beakers at the moment, and it should therefore be a priority in a work such as this to begin with a fair statement of the issues. As it is, for much of the book — until the last chapter in fact — Harrison skates over the difficult question of Beaker interpretations with brief, throw-away allusions, and in so doing is hardly fair to those who have been trying to open up the whole question to review. For example, on p.11 he is decidedly disparaging about the suggestion that Beakers may have been central to a beer drinking cult, but on p.15 they may "have been status symbols . . . perhaps on account of a special drink", and on p.69 "Bell Beakers could also have derived their importance from their contents, such as beer, mead . . .". If he looks again at what S.J. Shennan and I wrote in *British Archaeological Reports* in 1976, he will see that our concern was not to set up alternative models to explain Beakers, but to show that there are explanations, other than ethnic ones, which will fit the evidence. Harrison, like some others, has seized on the evocative peyote/beer suggestion, but does not mention the equally relevant Butt Beaker analogy.

The author's preoccupation with the Beaker aspects of this phase of prehistory results in much of the book being a rather dreary regional catalogue of contexts and sites in which Beakers occur. How much more illuminating it would have been had he remembered his sub-title, and con-

sidered the local background. As it is the Beakers too often float in a vacuum. The reader will find it nearly impossible to grasp how they relate to regional cultural developments, for frequent allusions make it clear that Beakers were absorbed by local populations and adapted to suit local circumstances. Thus Myrthøj in Jutland is a "Bell Beaker settlement" (p.35), but only one house had Beakers. Local Late Neolithic pottery dominates, but where does it fit in? In Hungary, the Beaker is intrusive in local Vučedol contexts, while over the Eastern Beaker province as a whole "between 80% and 90% of all pottery found in Bell Beaker graves [sic] is not actually of a beaker shape at all [my italics], but small cups, jugs, bowls and jars". So why should these be "Bell Beaker graves" and Myrthøj a "Bell Beaker settlement"?

What is needed here, if ever we are to make sense of the Copper Age in Europe, is a radical change in thinking. These are not "Bell Beaker" graves and settlements, but the graves and settlements of whatever local cultural group is involved, which happen to incorporate Beakers and Beaker influence to varying degrees. Usually Harrison at least acknowledges a local cultural element, for example in southern France (pp.114-116), and especially in Italy (p.123), where recent discoveries offer a good chance of putting Beakers into proper perspective. Alas, in Britain and Ireland, Harrison opts for the traditional Beaker invaders. "Bell Beaker settlements", as at Newgrange and Knowth, are mentioned without making it clear that only a fraction of their pottery is classic Beaker; a lot of it is decidedly *sui generis*, and the rest local in character. For me, the treatment of Britain is particularly disappointing: the author fails to examine objections to a distinct Beaker physical type; he does not scrutinize critically the so-called Beaker innovations; and he appears not to appreciate the supreme importance of the Lanting and Van der Waals regional approach, not just for British Beakers, but for later British prehistory generally.

It would be churlish not to compliment the author on his choice of illustrations, which make clear the skill and patience which went into producing Beakers; and as a panoramic view of the variety of regional Beaker styles this book will be invaluable. But Harrison's aim is to "give an intelligible account of the Copper Age in Western Europe" (p.6) and he does not seriously attempt the task. It is a perilous time to write on the Beaker phenomenon, but suicidal not to have a clear idea in one's own mind beforehand of what Beakers are all about. I confess that I would not be so rash as entirely to dismiss the Wee Folk; but I have no such qualms about the "Beaker Folk". □

Colin Burgess is Staff Tutor in Archaeology, Department of Adult Education, University of Newcastle upon Tyne, and author of *The Age of Stonehenge* (Dent, 1980).

Mummies: new light on ancient societies

A. Rosalie David

An X-Ray Atlas of the Royal Mummies. Edited by James E. Harris and Edward F. Wente. Pp.403. ISBN 0-2263-1745-5. (Chicago University Press: 1980.) \$55, £33.
Mummies, Disease and Ancient Cultures. Edited by Aidan and Eve Cockburn. Pp.360. ISBN 0-521-23020-9. (Cambridge University Press: 1980.) £25, \$45.95.

GRAFTON Elliot Smith, Armand Ruffer, and Alfred Lucas led the field in the application of their disciplines — anatomy, histology and chemistry — to the study of ancient Egyptian mummified remains in the early part of this century. Since then, there has been a continuing interest in the use of medical and scientific techniques to amplify historical and literary knowledge of family relationships, the existence of disease, living conditions and funerary practices in this ancient civilization. Recent technological advances have encouraged further multi-disciplinary research, and the study of mummies has provided the Egyptologist with new information.

The discovery of the Egyptian royal mummies of the New Kingdom period (c. 1675-950 BC) was an archaeological find of considerable significance. The pharaohs and their queens, buried with great ceremony in rock-cut tombs at Thebes in Upper Egypt, were soon disturbed by robbers; their tombs were plundered and their mummies stripped of precious amulets. The high-priests of the god Amon re-buried many of these royal mummies in two resting places — the shaft of a tomb near Deir el-Bahri and a side chamber in a King's tomb in the Valley of the Kings — in the vicinity of Thebes. Here, they remained undisturbed until the chance discovery of the two caches in AD 1871 and AD 1898.

The mummies were subsequently removed to the Cairo Museum, where they were unwrapped and investigated by archaeologists and anatomists in 1889 and in 1912, when G. Elliot Smith produced his definitive anatomical work entitled *The*

Royal Mummies. This included the examination of kings, queens, princes, princesses, priests and some unidentified individuals. However, having the opportunity to examine only one of these mummies with radiographic techniques, he stated that "... examination with the aid of X-rays would, no doubt, have provided much additional information and I hope this will be done at some future time ...".

This opportunity did not arise until 1967, when the University of Michigan, which had previously collaborated with Alexandria University in a radiographic survey of the skulls of an ancient Nubian people, was invited by the Egyptian authorities to X-ray the royal mummies in the Cairo Museum.

Their aims were to add to historical and literary sources relating to the chronology of this period and to the lengths of the rulers' reigns; to assess the health of each individual; to check the reality of the royal sculpture and art forms against the physical evidence of the mummies; and, using a portable X-ray cephalometer, to determine the craniofacial variations and the degree of physical heterogeneity evident in the pharaohs and queens of the New Kingdom.

The *Atlas* provides the long-awaited reference work (a popular interim account by J. E. Harris and K. R. Weeks, *X-Raying the Pharaohs*, was published in 1973 by Charles Scribner's Sons). It does not give a detailed description of each mummy, but, in addition to the illustrative material, uses a series of self-contained chapters to highlight features of this unique collection. The chapters reflect the individual interests of the multi-disciplinary team, and include techniques of mummification, the practice of medicine and dentistry in ancient Egypt, evidence of physical and dental disease in the royal mummies, radiological techniques and findings, the genealogy of the Royal Family and craniofacial variation, and the age at death of the New Kingdom pharaohs (here, Egyptological and

Mummy of King Ramesses II, nineteenth dynasty.

From X-Ray Atlas of the Royal Mummies

physical evidence, sometimes at variance, is assessed separately). Such an approach, as admitted by the editors, results in a degree of repetition and an overlap of material in some instances. However, it is useful and interesting to see the physical and historical evidence summarized independently.

Another difficulty which the investigators faced, because of the paramount consideration for the safety of the royal mummies, was the necessity of examining the mummies in their modern wooden cases in the museum, instead of under near-ideal conditions in a modern radiology department where sophisticated equipment and a variety of radiological techniques would have been available. There is a consequent lack of quality in the X-rays and possibly in the completeness of the evidence obtained.

However, some of the most interesting results included the observation that, unlike certain other Egyptian mummy collections, these royal mummies showed a marked degree of cultural and genetic heterogeneity. This reflected the presence of foreign princes and princesses in the Egyptian royal family of the New Kingdom rather than the averred custom of royal consanguineous marriages undertaken to ensure succession to the throne. Another tentative conclusion, reached through the use of scientific techniques, was that a mummy known previously as the "Elder Lady" was in fact probably Queen Tiye, a close relative of Tutankhamun.

Nevertheless, the caution which historians should observe in utilizing the results of such scientific investigations is well illustrated by one of the conclusions drawn here. This concerns the proposed relationship between the pharaohs Amenhotep III and Tutankhamun. Previous investigations of the mummies attributed to these kings, undertaken by Professor R. G. Harrison and his colleagues, and based on palaeoserological and anatomical observations, had indicated that Amenhotep III was probably Tutankhamun's father. However, a different conclusion is drawn here: "The cephalometric X-ray records would not support the . . . contention. It is most improbable that the mummy designated Amenhotep III was the biologic father of King Tutankhamun".

The second book reviewed here, *Mummies, Disease and Ancient Cultures*, deals with a wider range of techniques and also shows how a variety of societies have preserved their dead, either unintentionally or by artificial methods, as "mummies". This study again shows the value of a multi-disciplinary approach. In the long term, it is hoped that the work will go some way towards answering questions concerned with the origin of diseases and their evolution in different societies. To this end, the team is committed to a detailed pathological study of world-wide collections of mummies.

A summary is given of the work to date, and although Egyptian and South American mummies have received most detailed attention at present, a survey of other mummified remains is included — those discovered in the United States, the Aleutian Islands, Alaska, the bog bodies of Denmark, mummies in Australia and Melanesia, and Japanese examples.

A complete section is devoted to reports of the techniques involved in this study which include physical anthropology, radiology, histology, electron microscopy, palaeoserology and palaeobiochemistry. Not only does the book illustrate the various methods — heat-drying, freezing or the application of dehydrating agents —

by which a body can be preserved, but it also shows how diverse are the religious and environmental reasons which bring about mummification in different parts of the world.

Both books reflect a resurgent interest in the application of scientific techniques to the physical remains of ancient societies, which, used with due caution and appreciation of the possible fallability and limitations of such investigations, can provide the historian with a valuable additional insight. □

The cradle of geology refurbished

John Sutton

The Geology of Europe. By Derek V. Ager. Pp.560. ISBN 0-7084-115-2. (McGraw-Hill: 1980.) £16, \$38.40.

IN MY opinion this is much the best account of the geology of Europe to have appeared since Gignoux published his *Géologie Stratigraphique* over 50 years ago. Derek Ager describes his subject as Europe seen by a stratigrapher-palaeontologist. He treats his material very differently from Gignoux and the contrast is illuminating. Gignoux drew nine-tenths of his examples from Europe, and, in so doing, produced a comprehensive account of its geology which started with the oldest rocks, proceeded through younger formations to the most recent, providing abundant stratigraphical successions and the like on the way. Ager throws this approach out of the window; there is hardly a stratigraphical table in the book, so that he has space for much else.

Ager divides Europe into four regions on the basis of the relative ages of the last extensive period of metamorphism and deformation to have affected them. The geological history of each region is then described from start to finish — a method which brings out relations of older and younger events particularly well. Each of the four sections ends with a concluding chapter a few pages long. I was particularly struck with Ager's concise, five-page summary of Precambrian Europe. Although, as he puts it, "the Precambrian history of our continent is for the most part lost in the mists of metamorphism", he packs a telling account into that brief chapter.

The main virtue of this book is the way in which it brings together details to give a geological picture on a continental scale. Derek Ager has an interesting approach to geophysics; he appreciates "the hurricane of fresh air that new geophysical thoughts breathed into our subject". He goes on to write what is one of the best accounts of

any continent, set out on precisely the scale which would make it possible to compare the geological history of basins and uplifted crystalline blocks with the results of geophysical surveys. Such comparison, however, he leaves to others. He gives a good defence of his treatment, and in his introduction makes the point that any additional matter has to be balanced by the omission of something else. However, in a second edition I would hope at least to see a discussion of outline gravity and magnetic maps, and an account of crustal thickness.

Of all the continents, Europe is probably the most difficult to handle. Its geology is discussed in 20 languages, it is criss-crossed by frontiers and its complexities are probably the most apparent of any continent. Ager sails through all these difficulties triumphantly. He has travelled the continent repeatedly, he lists friends and helpers in every country; he is bold in his summaries and he writes with great clarity, and is not afraid to say what he thinks is important. Personal touches abound; we hear about the view from his study window and the nature of the rock surmounting the Ager garden gate. Historical figures pop up from time to time: Drake's game of bowls and the sailing of the Pilgrim Fathers illuminate the account of Plymouth Hoe. Whether, in consequence, one remembers which stage of the Devonian outcrops below the turf is probably a matter of individual experience. I expect every reader will find some of the allusions obscure; there are plenty of traps for the translators who will certainly get to grips with this most useful book. Unless they know their Sherlock Holmes and Irish mythology, we may yet see *chien de chasse des Basquervilles* and *Blarneystein* among the faunal lists and formation names of the future. □

Clocks in grandfather's rocks

G.Y. Craig

The Abyss of Time: Changing Conceptions of the Earth's Antiquity after the Sixteenth Century. By Claude C. Albritton Jr. Pp.251. ISBN 0-87735-341-7. (Freeman, Cooper: 1980.) \$12.75 US only.

THE essence of this story is quite dramatic. The calculated age of the Earth has increased from a little less than 6,000 years to more than 4,500 million years in the last three centuries. The Earth, of course, has remained untouched by this spectacular revolution apart from the addition of these few hundred years. What *has* changed has been the consensus of opinion by philosophers, theologians, physicists, geologists and evolutionists as to how old the Earth actually is; and it is salutary to be reminded by younger colleagues that estimates of the age of the Earth have doubled even since I was a student in the 1940s. Most fortunately this precipitous rate of ageing seems to have stopped.

The two main ways of looking at the passage of time in geology are not dissimilar from the ways in which we recall our own lives. Events can be put in a rough sequence and then, often with difficulty, slotted into the calendar ("Remember that

The discovery of radioactivity at the end of the last century led to increasingly precise radiometric dating of those rocks containing suitable isotopes; and the two scales, relative and radiometric, can now be correlated to provide a chronological scale of historical geology. This scale is still being extended and refined. Metamorphic rocks in Greenland, for example, have recently been dated at 3,750 million years, the oldest rocks so far discovered.

Dr Albritton's account arose out of a series of lectures given to students and staff at various academic institutions in the United States. The slim, attractively bound text follows the traditional and by now well-worn path through the maze of geological time by examining the contributions of its protagonists. Leavened by portraits and anecdotes, it is easily read and clearly reveals the influence of religion, conceit, catastrophe, fanaticism, feuds, ignorance, intuition, rocks and radioactivity on the evolution of the concept of geological time.

In spite of jazzy chapter headings — Malta's cradle; Solids within solids; Mr Hook(e); A sacred theory of the earth; Telliamed's story; The epochs of nature; View from the brink; Father William; The four-dimensional jigsaw puzzle; A question of tempo; A plenitude of events; The great tree of life; Kelvin; A numbers game; Radiometric dating; World enough and time — the leading actors are readily unmasked. For the reader who does not care to play this game, the protagonists turn out to be Steno; Hooke; Burnet; De Maillet; Hutton; Smith; Werner and other early stratigraphers such as Sedgwick and Murchison; catastrophists and uniformitarians (I've now broken a New Year resolution not to use that word!) especially Cuvier and Lyell; observers of volcanoes and glaciers (Scrope and Agassiz); Darwin; and lastly late-nineteenth and twentieth century scientists. Pleasingly, the book includes an appraisal of Arthur Holmes' brilliant contributions to the construction of a geological time-scale. The last chapter contains a typical student-textbook analogy: by compressing the major events of the Earth into 365 days, primates appear on Christmas Day and *Homo sapiens* arrives a mere hour before the dawn of the New Year. Dr Albritton is obliged to devote part of this chapter to a rebuttal of creationist dogma, now so common in parts of the States. Such concern is understandable for he teaches in Texas where fundamentalist views are not unknown.

Yet somehow the excitement of what should be a gripping story is not there. In one form or another it has all been done before, albeit with the historical anecdotes cut to a minimum. Last year two long articles by John MacPhee in, of all places, *The New Yorker*, conveyed a similar

William Thomson, Baron Kelvin (1824–1907). Detail from a cartoon in *Vanity Fair*.

summer when we went to Brittany and Aunt Doris got . . . Now what year was that?). And so it is with rocks. Geologists during the nineteenth century pieced together a sequence of geological events which enabled them to construct a relative time scale. Concurrently various attempts were made to establish when these events occurred and especially how old the Earth might be. Such calculations involved rates of erosion and deposition, the rate at which salt is being added to an already salt sea and the rate at which the Earth appeared to be cooling.

message but in a more entertaining style, perhaps because his serious but flowing story was laced with irrelevant cartoons and adverts including fast cars, whisky, cameras, jewellery and beautiful women, but more probably because he linked history with current field-work in different parts of the States.

James Ussher, Bishop of Armagh — calculated the date of creation as 4004 BC.

So here I am, vaguely dissatisfied with a perfectly adequate book simply because of a feeling of *déjà vu*. How can one be constructive? More might have been made of Archbishop Ussher (1581–1656) and his method of calculating the date of creation (4004 BC) and such subsequent events as the grounding of the Ark on Mount Ararat on May 5, 1491 BC (a Wednesday!). His chronology was incorporated in the most widely read book of the day — the King James VI bible — and so had an undue influence in Protestant countries. Many of the subsequent philosophical and scientific investigations described in the *Abyss of Time* were carried out in the shadow of Ussher's precise chronology. Astronomical calculations and coral clocks are not referred to but they show that the Earth is now rotating more slowly than it did during the Devonian when a year was all of 399 days. Above all, data from meteorites and Moon rocks reveal fascinating events earlier than any now preserved on Earth and provide independent factual evidence of the great antiquity of our Solar System and planet. They could have been the subject of a separate chapter.

And what of the future? The abyss is just as much in front of us as behind. The Earth is steadily losing its heat. As it continues to cool the lithospheric plates will thicken and stop moving: eventually there will be no more volcanic activity and no more earthquakes, but the land will continue to be eroded seawards, there to remain because uplift will no longer occur. The rock cycle will finally have come to an end: but there is perhaps consolation in the fact that the Sun will continue to shine until in another 5,000 million years it too becomes cold. And after that? But Albritton does not indulge in such fantasies. □

Trap for the unwary

William H. McNeill

The Fates of Nations: A Biological Theory of History. By Paul Colinvaux. Pp.383. ISBN 0-671-25204-6. (Simon and Schuster: 1980.) \$12.95 US only.

FOR the intellectual wanderer, impatient with the myopia of specialization, there are great risks in invading an unfamiliar turf. Jealous experts lie in wait for the newcomer to display his ignorance of their discipline by some slip of tongue or pen, and the complications of the new subject may not conform readily to the insights the newcomer brings from some other discipline.

This, unfortunately, is the case with Paul Colinvaux's book, *The Fates of Nations*. Colinvaux is an ecologist whose speciality is Ice Age Alaska and the land bridge which once allowed animals and plants to migrate from Asia to America across what is now the Bering Strait. For general readers, however, his best-known work is a summation of recent ecological niche theory which goes by the catchy title *Why Big Fierce Animals are Rare* (recently issued in paperback by Penguin). As an historian, who, like Colinvaux, has found it irresistible to wander across recognized disciplinary boundaries, I found this essay instructive and persuasive. But now when he takes on my own field of expertise, the human past, and seeks to illumine it by bringing ecological niche theory to bear, I find Colinvaux's ideas inadequate and his information radically defective.

As he engagingly explains at the end of the book in a "Note on Sources and Substance", he began to think about a "formal theory of history" in 1971, relying on the history "which is the common knowledge of Christendom", i.e. on what he remembered from his school days in England. This he reinforced by reading Toynbee's "overview of history's facts", and by consulting a few experts on battles — Livy, Tacitus, Arrian — as well as more modern writers like Liddell Hart and J. F. C. Fuller. He found the barrister Edward Creasy's *Fifteen Decisive Battles of the World*, first published in 1854, especially useful, while Field Marshal Montgomery's *A History of Warfare* supplied him with "the clearest insight into what gave victory in many a crucial battle". Thus, as Colinvaux tells us himself, his method of mastering history was studiously to disregard what professional historians have been doing since World War I to modify the patriotic and political history so ably caricatured in *1066 and All That*.

With *1066 and All That* plus school-boy Latin as his guide, and Toynbee as guarantor of "facts", what does an intrepid ecologist discover in the human past? The answer is a rhythm of rise and fall, predictable in the light of ecological niche theory. It may be summarized as

follows. Initially, history starts when a group of human beings develops a new technique that allows them to enlarge the ecological niches in which they live. This leads to a rise in population, for human beings have always pursued a breeding strategy — the large young gambit — that requires each breeding couple to raise as many children as they think they can afford. This strategy, Colinvaux assures us, has never altered, though he does not assert that it is instinctive.

Once enlarged niche spaces start to fill up as population increases, the prospering community faces a crisis. Since growing numbers with no increase in resources will force them to accept narrower niches again, they must look abroad to find the means to sustain their heightened expectations. Trade, colonization and aggressive war, aimed at taking land away from those in possession, are the alternatives such a population faces, and this is what history is all about. Successful communities expand and create empires; but sooner or later, expansion ceases. Colinvaux is completely silent on what stops expansion. On his principles I can see no reason for the process he sketches not to continue indefinitely, until the most successful aggressor has created an empire of the Earth. But the "common knowledge of Christendom" makes clear that a limit was set somehow, and Colinvaux shows his deference to facts by stopping the expansion of the Roman Empire at the Rhine and Danube — though, as I say, he gives no reason for this interruption of a process which he has declared to be both predictable and inevitable.

Once territorial expansion stops, the continued growth of population requires narrowed niches; and narrowed niches will be accepted only reluctantly by the population concerned. This means an oppressive government — a police state in fact, in which the rich, clinging to their broad niches, impose their power on the poor by dint of "regimentation, bureaucracy, class, rationing and caste" (p. 64). Such a regime is vulnerable from without, and eventually barbarian invaders, technologically abreast of the latest methods of civilized warfare, will succeed in destroying the oppressive regime by cutting off food supplies to the cities. The newcomers institute a barbarian pattern of life in which local consumers depend on local food production. This sharply reduces the total number of inhabitants, since the urban masses, congregated under the regime of civilization into vast cities, are unable to maintain the breeding strategy that had hitherto led to an ever-mounting population. They simply die off, leaving a sparsely settled countryside to start the cycle of civilization over again.

Echoes of Toynbee's cycle are obvious, though the emotive tone that Colinvaux's ecological vision imposes is utterly at odds with Toynbee's humanistic and religious values. There are, too, some serious anomalies in this thesis, for the modern cycle of civilization does not conform closely to the classical Mediterranean pattern.

An even greater anomaly is introduced in Colinvaux's final chapter "The Shape of Things to Come". After exploring the implications of this theory, which predicts that growing populations will launch aggressive war in order to maintain enlarged ecological niches, he apparently reverses himself by saying that it "may well be that our breeding strategy will yield even smaller families for the moderately affluent than they have now" (p. 313), since one may hope that "new roles for women will hold down the population and let us all live in freedom" (p. 314). So because "we breed in human and controllable ways" and can understand what is happening to us, we "need fear neither our future nor our fate" (p. 321). But if human breeding strategy is alterable now, why not in the past? And if one group of people in this twentieth century does decide to have fewer children in order to maintain broader niches, what prevents others from breeding incontinently and filling in the space occupied by the rich and continent, not by conquest, but by the less spectacular method of in-migration?

This sort of population shift is occurring before our eyes, as *Gastarbeiter* in Germany, illegal aliens in the USA and Asians in England attest. It occurred in distant ages as well. The replacement of Sumerian speakers by Semites in ancient Mesopotamia in the 3rd millennium BC and the bitter jibes of the Roman poet Juvenal against the Greeklings whom he saw taking over favoured places in Roman society, are only two examples of the past importance of peaceful migration. Indeed, all great imperial cities of times past have been polyethnic in their population. They were places where diverse peoples congregated and died off due to the intensified disease exposure involved in urban living before the days of modern sanitation. Colinvaux seems unaware of this traditional population dynamic, well attested though it is for early modern Europe when statistical records begin to become available to historians. Indeed he is ignorant of all historical demography, though for a theory that puts such emphasis on population growth as the fundamental disturber of history he surely ought to have guarded himself against the sort of reproach I make of his procedures by at least consulting a few elementary textbooks on historical demography. If he had done so, he would have discovered that historians are agreed that the population of the Roman Empire declined sharply in the second and third centuries AD, recovered partially in the fourth century and then plummeted again in the fifth. Colinvaux's

picture of an ever-rising population pressing harder and harder on available niches therefore runs counter to all modern historical scholarship.

As a matter of fact, Colinvaux is aware of some of the signs of depopulation that manifested themselves in late Roman times. But he dismisses empty fields and unoccupied border regions where Roman authorities settled barbarian tribesmen from beyond the frontier as a predictable consequence of population growth! The argument is sufficiently bizarre to deserve quotation in full:

From the time of troubles onward the population shifts within the state. There is a drift from the land as peasants are displaced in the interests of increased production. This happened in ancient Greece and Rome no less than in the time of the enclosures in Tudor England, or in modern industrial states. The process can be seen in the development of every civilization. Feeding great numbers of people is more easily done if they are brought together in dense settlements; running the agriculture needed to supply these dense settlements is more efficient in the larger agricultural units of agribusiness. And the "drift from the land" is a predictable consequence of a dense population growing denser [pp. 83-84].

To test this hypothesis one might look for some indication of the growth of cities while fields emptied out. Roman cities from the 3rd century onward conveniently provided such an index by erecting ring walls necessitated by the declining level of public security in the empire. By modern standards these enclosures were tiny indeed, and diminish with each rebuilding. Where is the massive, ever-growing urban population Colinvaux's theory requires? Even on a purely theoretical level, and without the vulgar appeal to mere data, one would suppose that before propounding his ridiculous hypothesis Colinvaux might have asked himself how it could be more efficient to carry food from the fields to distant urban consumers (in ox carts presumably), and how "agribusiness" could plough and reap in the absence of modern machinery, and without numerous labourers on the spot to do the work. The fact is that human populations rise and fall in complicated and only partially understood ways, and in response to a far wider range of shifting conditions than Colinvaux's system admits.

My judgment of *The Fate of Nations* is that in venturing beyond the boundaries of his discipline Colinvaux has come a cropper. This is a pity, for surely there are useful things historians might learn from ecologists, and an ecologist who took the pains to acquaint himself with historical literature might indeed be in a position to shed new light on familiar historical conundrums.

William H. McNeill is Professor of History at the University of Chicago, and author of *The Human Condition* (Princeton University Press, 1980).

THE EARTH'S PROBLEM CLIMATES

Second Edition
by Glenn T Trewartha

In this new and extensively revised edition, the author takes into account new information and climactic data that have become available since the original edition appeared in 1961.

Trewartha offers an inventory of the more important of the earth's problem climates, brief and concise descriptions of their characteristics, and suggested explanations for at least some of them; in so doing, he draws together the results of numerous definitive studies in dynamic climatology.

SCIENCE AT THE WHITE HOUSE

A Political Liability

EDWARD J. BURGER, JR.
foreword by DON K. PRICE

From the day the first atomic bomb was dropped, scientists gained a new image in the public's eye. In the succeeding decades, there seemed to be no limit to what technology could accomplish, from military weapons to moon walks. *Science at the White House* looks at what happened when America's new experts were called in to serve as advisers to the president.

As cases in point, Burger assesses the government's efforts at planning for key issues that emerged during his tenure as a science adviser: issues concerning national health care, environmental regulation, and population and family planning, among others. 208 pp, £9.00.

One hundred years of the Natural History Museum

D.T. Donovan

Alfred Waterhouse and the Natural History Museum. By Mark Girouard. Pp. 64. ISBN 0-300-02578-5. (Yale University Press: 1981.) Hbk \$12.95, £4.95.

Alfred Waterhouse, 1830–1905, from a portrait by Sir William Orchardson.

THE Natural History Museum is the most splendid of the South Kensington museums; it has a vigour and coherence which is a tribute to the architect Alfred Waterhouse. So it comes as a surprise to learn that the building has a complicated history, and was nominally designed by somebody else.

The natural history collections were for long kept in Bloomsbury with the books and antiquities of the national museum. By the early nineteenth century antiquities were being added in large quantities, and by mid-century many thousands of natural history specimens were accumulating every year. The new British Museum building, begun by Robert Smirke in about 1823, was already too small by the time it was completed in about 1850.

Mark Girouard begins his account with

Richard Owen's vision of a great new museum in 1858, which was the origin of the present building. Removal of the natural history departments from Bloomsbury had been considered for some time, though a practical solution was not found until after 1851 with the development of South Kensington as a centre for education in the arts and sciences.

Owen, already famous for his contributions to comparative anatomy, had been appointed Superintendent of the Natural History Departments in 1856. In the same year, Antonio Panizzi, Keeper of Printed Books, was made Principal Librarian (i.e. Director) of the museum. Panizzi had long wanted to get rid of the natural history departments, and said so on every possible occasion. Yet even with Owen and Panizzi working towards the same end, it was another 25 years before the natural history collections were actually moved out of the Bloomsbury building. Initially, at least, almost the whole of the scientific establishment was opposed to such a move, and succeeded in influencing Parliament against it for some time.

In 1863, however, the Government bought the present site. On it stood the exhibition building of 1862, built by the official architect Francis Fowke, and widely disliked. Parliament refused to purchase this building, which was demolished, and an architectural competition for a great new museum complex was held in 1864. It was won, to everyone's surprise, by Francis Fowke, but he died before his plan could be executed.

Alfred Waterhouse, newly arrived in London from successes in Manchester, was appointed to carry out Fowke's design, but it was not until 1873 that building was started. By this time only the Natural History Museum — about one-quarter of Fowke's complex — was actually going to be built, so the building had to be drastically re-designed. Girouard traces the

influence of Fowke's design by comparing successive versions of the building. However, there is little perceptible resemblance between Fowke's drawings and the present building, and Waterhouse's standing as the architect is fully justified.

The plan of the museum, however, is neither Fowke's nor Waterhouse's; it stems from a sketch by Owen in 1859. This shows main east–west galleries with numerous galleries opening off them at right angles, the arrangement in the present-day museum.

Owen had always wanted his museum to be enriched by appropriate decoration. He and Waterhouse devised a scheme in which representations of living animals and plants adorned the west wing, intended for zoological collections, and extinct ones (restorations, not fossils) the east wing, where fossils and minerals were to be housed. Waterhouse's drawings were translated into models and cast in terracotta; comparative pictures in the book show how faithfully this was done.

The book has been sponsored by the Museum as part of the celebration of the centenary of its opening in 1881. This centenary is, unhappily, marked by controversy over the current proposal to demolish the rear single-storey galleries, thus destroying Owen's original plan.

Mark Girouard has written an attractive and interesting book which explains the history of the building and its architectural origins. It is well illustrated with pictures of the museum as it is, Waterhouse's working drawings and earlier versions of the design. Only the photographs of the interior are disappointing and do less than justice to the building. Otherwise, the book makes a handsome souvenir of this great embodiment of Victorian scientific achievement. □

D.T. Donovan is Professor and Head of the Department of Geology at University College, University of London.

As it might have been — the winning, but unexecuted, design submitted by Francis Fowke in 1864. On the death of Fowke, Alfred Waterhouse was appointed as architect and the museum was built largely to his designs.

Intellectual cross-fertilization and evolution

A.J. Cain

The Evolutionary Synthesis: Perspectives on the Unification of Biology. Edited by Ernst Mayr and William B. Provine. Pp.487. ISBN 0-674-27225-0. (Harvard University Press: 1980.) \$25, £15.

THIS book looks out upon an incredibly rich panorama of personalities, groups, institutions, countries, attitudes, theories, arguments, experiments, facts, false facts (even a very few artefacts), misunderstandings, barriers emotional, linguistic, dogmatic and intellectual, all adding up to one of the greatest intellectual advances of our time — the unification of different biological sciences by a single neo-Darwinian theory of evolution in the first half of this century. Some of the principal actors have contributed invaluable accounts of their own roles: among them are Mayr, Simpson, Dobzhansky, E.B. Ford, C.D. Darlington, Curt Stern; and there are extremely valuable surveys and analyses by biologists, historians and philosophers (Lewontin, Gould, Mark Adams, Dudley Shapere etc.). The book itself is now history and, since the 1900–1940 period qualifies as history (not merely as out-of-date), it will inspire and provoke an ebullition of PhD theses, papers and books worse than the great Wittgenstein industry. One of the virtues of the book is that while making thoroughly clear the limitation of science by the inadequacies of personalities, institutions and governments, it does present beautifully, especially in genetics and cytology, the intellectual impact of actual scientific discoveries and their role in changing people's thinking.

The book is organized by subjects (Part I, cytology, embryology, systematics, botany and so on) and by countries (Part II, Russia, Germany, England, France, USA), with a concluding survey (no, I will not say "overview") of the whole subject and a miscellany of very useful biographical contributions, rather over-titled as "Biographical Essays".

Especially valuable to those with little German and less Russian is the survey by countries, and a saddening spectacle it presents; the superb beginning in Russia, based on an excellent naturalists' tradition of population genetics, aided at first by the ideals of education and especially science during the Revolution, then brutally terminated as a result of the charlatan Lysenko's power-politics. France did not contribute at all to the synthesis except for Teissier's and L'Heritier's invention of the population cage and work on balanced polymorphisms. Both started as mathematicians (the probable reason for Teissier getting his chair at the Sorbonne is fascinatingly non-scientific), uncontaminated by the ideas of the French Establishment.

Both Boesiger and Limoges have some very hard things to say about the academic establishment in France, and, so far as I can see, they are thoroughly justified. Boesiger remarks "France today (1974) is a kind of living fossil in the rejection of modern evolutionary theories; about 95 percent of all biologists and philosophers are more or less opposed to Darwinism."

Limoges comments equally astringently on the language barrier, the closed university system ("no one can hold a chair in a French university who is not French and who does not have a French doctorate") and the centralization of the system, providing for career control by a few senior professors in Paris. Although that has now been considerably modified, Boesiger emphasizes the centralized control of the research organizations. One can add that there is considerable pressure on French workers to publish in French. Certainly there are in France today some excellent and up-to-date evolutionists — one thinks immediately of Maxime Lamotte in Paris, and a botanical group at CNRS Montpellier, as well as Zuckerkandl and others at that university; nevertheless it seems to be true that a largely self-perpetuating Establishment, accepting only conformist successors, has made France, as far as evolutionary studies go, into an intellectual island. Yet the new recruitment every year of fresh minds is one of the most valuable processes in any intellectual society.

Germany is well treated by Mayr, Rensch and Hamburger. Mayr brings out important administrative limitations (not enough chairs and the nature of professional duties), Curt Stern the difficulties of institutions separated by distance (Berlin-Buch and Berlin-Dalhem!). Little is said about Nazi influence. Rensch, in an essay very sympathetic to his predecessors and colleagues, brings out many reasons for the slowness of the synthesis in Germany — apparently contradictory phenomena in genetics and palaeontology, speciation apparently concerned only with trivial characters, the apparent internal drive of the organism in development and regulation, independent of the environment, religious convictions and so on, which, however, operated elsewhere as well. The slowness of penetration of genetical results in Germany certainly needs study.

Hamburger brings out a further point (which Boesiger applies also to Cuénot in France): "the widespread German tendency to have a unified *Weltanschauung*, a more general overview of metaphysical and scientific creeds than just having *Weltanschauung* and scientific work compartmentalized side by side".

The history of the evolutionary synthesis in the USA is particularly well treated, and deservedly so, and there are many studies of that intriguing man T.H. Morgan and

Minerals from the Marine Environment

Sir Peter Kent, FRS

Resource and Environmental Sciences Series

A review of the full spectrum of mineral resources development as seen against the environmental background of the seas and oceans.

his close associates. The conversion of this school to a neo-Darwinian attitude by their own discoveries in genetics and karyology, powerfully aided by their openness to ideas and visitors from abroad, was, however, only partial in some cases because of the difficulties of extending genetical findings to macroevolutionary phenomena, including speciation. Mayr makes an especially important contribution in emphasizing that the synthesis was a synthesis; it was extremely difficult for many years to reconcile Darwinism and the new science of genetics, and it was systematists in particular who contributed the concepts of adaptive geographical variation, variation in whole populations under environmental selection, and partly adaptive speciation (a macroevolutionary process). Yet it must be added that it was largely the wholly unjustified insistence of many systematists that characters of species were non-adaptive that misled many of the earlier evolutionists into doubts about the efficacy of natural selection and the continuity of micro- and macroevolutionary phenomena.

Equally fascinating is the comparison between subjects. Botany (not the botanical part of genetics) was almost as poor a contributor among subjects as France among countries, and Ledyard Stebbins's article is as thought-provoking as Boesiger's or Limoges'.

When one stands back from it all, several major thoughts come to mind. The difficulties are highly instructive, but little more than one would expect in any intellectual controversy; indeed Simpson is probably right in indicating that given the human character, the synthesis was achieved about as fast as could be expected. But some topics are hardly touched on. I suspect (in a few instances, I know) that religious considerations came first, even if they were seldom expressed, in some scientists' minds, and conditioned heavily what they were prepared to accept scientifically. Under this heading I include humanism when it refuses the application of the synthesis to mankind, and of course Marxism with its leaning to some form of Lamarckism (only too well documented in this book).

Secondly, and allied to the preceding, the role of chance as an explanatory factor is hardly touched on — yet, on the one hand, as a means of explaining away inconvenient phenomena it has been invaluable as an alternative to natural selection; on the other, it has added to the revulsion of many people against natural selection that what the process has to work on is the effects of mere chance.

But lastly, there is almost no indication in the book that the recognition of natural selection as the major (or nearly exclusive) agent of evolution was ever due to any work on natural selection in the wild, except very indirectly. A simple-minded (or extremely intelligent) Martian might well think that if it was debated whether natural

selection operated in the wild, the thing to do was to go and look for it. Chetverikov might have done so if politicians had let him; Haldane thought it much too difficult. The whole debate over the efficiency of natural selection in the wild was conducted by argument over indirect evidence, and indeed to a large extent it still is.

The present book contains little material towards a history of actual field-work directly on natural selection, except for E.B. Ford's contribution — and perhaps rightly, since it seems not to have affected the synthesis. It does contain valuable hints towards a history of why no one has attempted it — for example, Lewontin's statement that "Wright's notion that random processes allow the exploration of the field of gene frequencies . . . frees the evolutionist from having to ask such

questions as why did some Ceratopsian dinosaurs have three horns and some have two and some have a frill and some not?". Of course it does nothing of the sort except to those who want it to. It was not *shown* in the first place that the development of different ways of fighting was due to any random process, except on the presumptuous assertion "Because I can see no sense in this phenomenon, not having worked on it, therefore it must be random". The use of random processes in explanation even at the present day is rather like John Henry Newman's use of St Augustine's text to precipitate him into the Roman Catholic church (see Geoffrey Faber's *Oxford Apostles*) — using a bad reason for doing what we intend to anyway. □

Avian evolution transcends philately

Alec Panchen

The Age of Birds. By Alan Feduccia. Pp.208. ISBN 0-674-00975-4. (Harvard University Press: 1980.) £12, \$20.

OF ALL those who concern themselves with the palaeontology and evolution of vertebrate animals, it is arguable that bird palaeontologists have taken on the most difficult task. The anatomical uniformity of the majority of bird species is such that the identification of their individual fossil bones varies between difficult and impossible; further, there are numbers of cases (some cited by Feduccia) in which the avian status of particular specimens is still a matter for debate. It is probably for these reasons that while popular books on dinosaurs are legion, a book on bird palaeontology is unusual despite the innumerable amateur ornithologists that are the mainstay of almost every natural history society. One would hope, therefore, that there was a market for a popular book like Feduccia's as evidence that at least some of these amateurs have interests extending beyond the prevalent stamp-collecting approach to bird watching.

On the whole Feduccia serves his potential audience well. However, his opening chapter tends to hop about its subject matter in a manner reminiscent of small birds themselves, starting with a scene-setting paragraph on *Archaeopteryx* — geologically the oldest as well as the most famous of all bird fossils — but then switching to bird anatomy, "Darwin's finches", adaptive radiation, the concepts of homology and analogy, the reconstruction of phylogeny and the geological time scale, before settling on an account of the several finds of *Archaeopteryx*, with useful photographs of each specimen.

In his second chapter he gives an account

of theories of the evolutionary origin of birds, a fiercely debated subject still. When dealing with controversial issues Feduccia is usually sensible and it is not his fault that at least one of the principal protagonists in this debate has changed sides since the chapter was written. Following chapters deal with the evolution of flight and then with the fossil history (such as it is) and evolution of all the major groups of birds.

Feduccia has been in the forefront of some of the phylogenetic work he describes and much of the book is authoritative. However, particularly in the early chapters, there are some things to take exception to. The layman's naive view of the course of evolution, as a highway from simple organisms to human beings with less important byways branching off, will be reinforced by statements such as "ornithischians [a dinosaur group] were highly specialised herbivores and far too removed from the main line to have given rise to any other major group". It will be similarly reinforced by the use of "Age of Reptiles", "Age of Mammals and Birds" and so on, as in "The cotylosaurs [the earliest reptiles in the author's (outmoded) usage] appeared long before the Age of Reptiles . . .". There are also a few obvious errors — how, for example, can the two views of the original *Archaeopteryx* feather, pictures on p.12, be "main slab" and "counterslab" when they are not mirror images of one another? Also, the patagium (flying membrane) of the living flying lizard genus *Draco* does not stretch "between the forelimb and hindlimb" (p.40): it is supported by elongate ribs alone.

On the whole, though, the book is easy and pleasant to read. The style is clear, concise and interesting, albeit with some infelicities — "Members of this classifica-

tion . . ." (i.e. taxon); "... third alternative . . ." — and the chapters are short. The bibliography is excellent; here Feduccia refuses to "talk down" to the reader and quotes every reference, not just "further reading". However, the illustrations although numerous are often disappointing. They include black and white photographs of specimens and localities, and a number of frankly mediocre original drawings by several hands, the low standard of which is emphasized by some of the splendid and

Reconstruction of *Archaeopteryx* by Rudolf Freund.

famous restorations by Heilmann, Charles Knight and others with which they appear. Many of these cry out for their original colours. Presumably the decision to exclude the use of colour was the publisher's rather than the author's; nevertheless I imagine that it will affect sales adversely. This is a pity as the book is otherwise well produced and certainly deserves an audience. □

Gorillas on a tightrope

Alison Jolly

The Natural History of the Gorilla. By A. F. Dixon. Pp.202. ISBN 0-297-77895-1. (Weidenfeld & Nicolson: 1981.) £16.50. To be published in the USA by Columbia University Press.

IF YOU want to know about gorillas, you need this book. Alan Dixon has summarized the present state of knowledge about all aspects of gorillas' biology from anatomy to conservation. Furthermore, he writes in a lucid, factual style which presents the information clearly to anyone from fifth form to professorial status, without either talking down or jazzing up.

The drawings (by Dixon himself) add both clarity and charm.

The book has several strengths. First, it deals equally with the results of laboratory work and results from the field. Dixon's own studies range from laboratory analysis of primate hormones and sexual behaviour, through the testicular atrophy of several adult male silverbacks in zoos (including Guy at London), to making field censuses of gorilla populations. He is thus well placed to appreciate both sides of the story. A second strength is the balance achieved between generalization and data from individual studies. In the chapter "How Close to Man?", he manages to explain quickly many of the bases of primate classification, sum up the evidence which suggests man's close relationship to gorilla and chimpanzee and the more distant relationship of these three African species to orang-utans, and yet include the divergent studies which indicate Asiatic, rather than African, origins for man. Similarly, when he describes wild populations, he includes data showing differences between the three gorilla subspecies, and even between western and eastern Virunga Volcanoes, adding appropriate caution about sample size. In a popular book, it is unusual to avoid generalizations about "the gorilla" meaning ten or twenty individuals on Mount Visoke.

Finally, Dixon covers the whole scope of the literature from Hanno (fifth century BC) up to 1980. This enables him to deal fairly with such experiments as Yerkes' on Congo (1926–1928), which is still one of the most complete accounts of a gorilla's problem-solving, as well as Redshaw's (1978) splendid Piagetian study of the development of infant gorilla intelligence. The conservation account is also up to date, to the death of Digit and others who had their heads and hands chopped off for tourist souvenirs.

The main reservation I have is that Dixon does not pursue his synthesis of detail quite far enough for my taste. I looked for a discussion of the relation of gorilla leaf-eating to metabolism, ranging and social structure, and comparison with the frugivorous orang and chimp. All the pieces are there, but Dixon does not explicitly link them up; similarly, reproductive strategy is split into several different chapters. This is clearly his choice — he gives us the data without fashionable theorizing, but he is better placed than most of us to deal with such theories.

I could also do with slightly more drama in the final chapter on conservation — perhaps some of Dian Fossey's emotion over Digit, or Alan Goodall's encounters with poachers in *The Wandering Gorilla* (Collins, 1979). Instead, Dixon has chosen restraint. Perhaps he is right that estimates of the remaining wild populations and their possible or likely extinction are even more horrifying.

The whole question of how to balance

professional against popular appeal bedevils primate studies. In the circumstances Alan Dixon's summary of the natural history of the gorilla for such a wide audience is laudable. Scholarly balance may seem faint praise until you add that it is balance on a very thin tightrope indeed. □

Alison Jolly is temporarily in the School of Cultural and Community Studies, University of Sussex.

Lure of the shore

J.T. Enright

Intertidal Invertebrates of California. By Robert H. Morris, Donald P. Abbott and Eugene C. Haderlie with 31 contributors. Pp.920. ISBN 0-8047-1045-7. (Stanford University Press: 1980.) \$45 US only.

This is a book for those who find the California shoreline at low tide a place of beauty, wonder and interest, and who want information on the common animals that live there. [Preface].

THE west coast of North America has one of the most diverse temperate-latitude intertidal faunas in the world. In California that fauna provides research material for dozens of marine laboratories and learning material for hundreds of high schools, colleges and universities. *Intertidal Invertebrates of California* is aimed at that limited — some might say, provincial — audience, but it could conceivably also lure naturalists from the entire world to view and study this showplace of diversity. Whether or not it eventually has that sort of incidental success, there is no question about its value and importance for the intended audience: every biologist, professional or amateur, who ventures into the California intertidal zone for the first — or the ten-thousandth — time should have this volume available.

Thanks to a grant from The David and Lucille Packard Foundation, the price is such that most users will be able to purchase their own copies. Even a first glance at the 200 photographic plates — all but three of them in colour, most with four to six separate portraits of the animals — will persuade the prospective buyer that this book is a bargain. The majority of the photographs were taken by Morris, but nearly 50 other naturalists contributed to the handsome illustrations. This portion of the book will be particularly treasured by all who find the "shoreline . . . a place of beauty [and] wonder".

With the photographs as the bait, Abbott and Haderlie, together with 31 other contributors, have provided nearly 700 pages of text, bibliography and index for those "who want information". Some 750 species are treated in detail in the 24 chapters. For each of entry, the text provides the classification of the animal; a morphological description, including

typical size and the features which distinguish that species from those with which it might be confused; and notes on habitat and geographical distribution, often with qualitative comments on abundance. Usually there is additional information on what is known of the animal's natural history. Each entry closes with literature citations, sometimes only one or two, in other cases several dozen. Detailed references are then provided at the end of each chapter.

The introduction suggests that this book was intended as a primary guide for identifying the animals, but this emphasis is, I think, misplaced; it will simply not do as a field manual. Its unusual format and sheer weight (about six pounds) militate against carrying the book along to the shore. Beyond the problems of getting book and animal together (since the reader is, rightly, urged not to bring specimens home with him), there are none of the traditional "keys" for identification; and the coverage is intentionally restricted to the more common and conspicuous elements of the fauna, meaning that using the plates and text for primary identification would be not only time-consuming but often misleading.

For field identification, then, one should instead take along Smith and Carlton's revision of *Light's Manual* (University of California Press, 1980). Thereafter, *Intertidal Invertebrates of California* can be treated as something akin to a biographical dictionary. Knowing, or at least having a strong hunch about the name of the creature, the reader can here confirm that he has, indeed, probably seen this or that member of the community, and then learn some of what the experts know about it, as well as where to find further information.

A conspicuous contrast with a biographical dictionary is that no historian is ever likely, on the basis of some arbitrary legal point, to decide that henceforth Madame Curie will be known only as Marie Skłodowska. Many of my old friends in the intertidal zone, however, regardless of how well established their reputations were, are now assigned names different from those I learned 25 years ago. In some cases (e.g. *Mitella polymerus* and *Aletes squamigerus*) the older names are also included in the index to this volume; but for others (e.g. *Acmaea digitalis* and several congeners, and *Lepidopa myops*) there is no hint about former identity. This is, of

course, not so much a complaint about this book as about the problems inherent in nomenclature, and it can be argued that such changes represent "progress"; but I sometimes wonder. . . .

The neophyte will find the chapter introductions and the detailed text entries in this book most useful; the more advanced student will find the literature citations a good starting point for a research project; everyone will, I think, enormously appreciate the coloured plates. The professional biologist who knows some part of the literature on a particular group or species will no doubt note — as I did —

cases of mistaken conclusions, incomplete or outdated citations, and unevenness in coverage. But it would be petty to emphasize such deficiencies. The central point is that this book is an indispensable addition to the library of all who are interested in the common intertidal invertebrates of the California shoreline — and it contains a very attractive collection of colour portraits for those who will never get there. □

J.T. Enright is Professor of Behavioral Physiology at the Scripps Institution of Oceanography, La Jolla, California.

Old twists to an old tale

Jerry Donohue

The Double Helix: Text, Commentary, Reviews, Original Papers. Edited by Gunther S. Stent. Pp.298. ISBN hbk 0-297-77899-4; ISBN pbk 0-393-95075-1. (Weidenfeld & Nicolson/W.W. Norton: 1981.) Hbk £10; pbk \$5.95.

AN OLD proverb, as given by Gibbon, tells us that "happy is the nation that has no history". If this applies to substances, then DNA, surely, is the unhappiest of molecules, for it is the subject of innumerable biographies.

This new book contains: the complete *The Double Helix*; reprints of 12 reviews of it from 1968 and discussions of these by Gunther Stent; reprints of three papers from *Nature* by James Watson, Francis Crick and Aaron Klug; three letters to *Science* from 1968 by Max Perutz, M.H.F. Wilkins and Watson (see below); reprints of six papers from 1953–54 describing the original DNA work done in Cambridge and King's; and a name index the usefulness of which is somewhat marred by careless inaccuracies.

Should the fact that only about 5% of the contents of this new edition is previously unpublished material be cause for discontent? Probably not, as it brings together *The Double Helix* and some of the important writings it spawned. There are, however, other causes for discontent which are hardly contentious. The original text of *The Double Helix*, including the photographs and diagrams, ran to 233 pages; in this reprint these occupy 135 pages. This drastic compression was accomplished by abandoning the elegant format of starting each chapter on a new page; by taking the plates of the first (Signet, 1969) paperback edition, which was itself a compression of the original, and compressing it still further by putting more lines per page; and by reducing the sizes of the photographs, some by more than 50%, so that the individuals in the group photographs are virtually unrecognizable. Also reduced in size is the photographic reproduction of an historic

letter of Watson to Delbrück which is legible only with great difficulty and, in some places, totally undecipherable, a circumstance not caused by Watson's crabbed hand. Surely a book as important as this deserves a better production.

Something very mysterious should also be pointed out. In the diagram on p.111 the enol structure for thymine incorrectly has an oxygen atom where there should be a hydrogen atom. The same diagram on p.191 of the hardback first edition of *The Double Helix* is correct, and identical in every other respect, right down to the pattern of dots inside the rings of the bases. Now, admittedly, some of the early difficulties in cracking the DNA structure concerned the keto-enol business, but what sinister force, in Alexander Haig's terminology, took it upon itself to change a correct structure to an erroneous one?

There are several misconceptions and misreportings that ought to be dispelled before remarking on a few of the reviews included in this new volume.

● *The Myth of the Invention of Base Pairing.* Throughout the reviews runs the thread of the notion that Watson and Crick would never have discovered their structure had it not been for "rules" of Erwin Chargaff that in DNA (molar amounts of) cytosine = guanine and thymine = adenine. However, Chargaff himself had not yet referred to this relationship as rules, and, indeed, his own published analytical data gave merely the merest hint of these regularities, and he himself averred the possibility that the regularities might be accidental. Stent (pp. 168–169) has more to say on this.

The fault for these misconceptions must be squarely on the shoulders of Watson. We find him writing (p.75) "The moment [Spring 1952] was thus appropriate to think seriously about some curious regularities in DNA chemistry first observed by Chargaff", and then subsequently cheerfully disregarding them, and building a like-with-like, non-complementary, model. In addition, he had been assured by his friend, the biochemist Markham, that if

Cold Spring Harbor Laboratory have recently published the proceedings of the symposium on viral oncogenes which was held last year. The two-volume set of proceedings, comprising Vol. XLIV in the series *Symposia on Quantitative Biology*, is available from CSHL, Fulfillment Department, PO Box 100, Cold Spring Harbor, NY 11724, or through booksellers, price \$130 (\$156 outside the USA).

Review of James Watson's *The Double Helix* by J. Field

Hear the song of how the spiral
Complex, twisted, double, chiral
Was discovered. Its construction
Following some shrewd deduction
Was accomplished. From all sides "Oh
Tell it as it was" they cried so
Then he took his pen and paper
And composed the helix caper
Writing of the Cambridge popsy
Turned the world of science topsy
Turvy like had not before been
Done. The story is no more than
How the structure was discovered
Secret of the gene uncovered
Biological prediction
Better than a work of fiction
Stylistically breezy
Everything appeared made easy
And it was. The bases' pairing
Found at last — a small red herring
Notwithstanding. How he found them

And the hydrogens that bound them
Was a stroke more accidental
Than a work experimental
Chemistry was not his calling
He had read *one* book by Pauling
Models of the bases he'd made
With them on his desk top he'd played
Shuffling them and putting like with
Like he made no lucky strike with
Guanine, thymine, adenine. A
Letter came from Pasadena
Horrors! then the day was won for
Pauling's model was quite done for
Extra atoms he had set in
Where no atoms should be let in
With some phrases less than modest
Pauling's model's called the oddest
Back now to the basic pairing
How's the structure building faring?
Faster, faster goes the race, then
Everything falls into place when

Tautomers which nature chooses
Are the ones our author uses
Two chains (but here we can't be sure)
Plus this extra structure feature:
Pauling's outside bases inside
Pauling's inside phosphates outside
Now they all were quite ecstatic
Soon became they quite dogmatic
Having nature's secret later
Checked against the x-ray data
This was difficult, for Rosie
Found our scientist rather noseey
Bragg compares the book with Pepys. Is
This the verdict of Maurice? His
Thoughts alas we cannot gainsay
Trumpet blowing's not his forte
Tales like this do have a moral
Whether printed whether oral
Find the right man to advise you
Then you'll get a Nobel prize too.

Chargaff said that guanine equalled cytosine, he, Markham, was equally certain that it did not, because Chargaff's experimental methods inevitably underestimated the true amount of cytosine. On numerous other occasions Watson refers to Chargaff's "rules".

It is, on the other hand, abundantly clear from the narrative that these "rules" had nothing whatsoever to do with the construction of the DNA model. The model came first, and made the rules, not the other way around.

● *The Myth of the Undercover Agent.* In some of the reviews selected by Stent the role which Peter Pauling played is displayed as not quite what it should have been. Thus Watson, according to Merton (p.215), reports "with temerity and self-mocking wit the occasions on which Linus Pauling's son, Peter, then a student at Cambridge, became a prime source of information about what his father was up to". Morrison (p.176) says that the idea for the double helix came "... out of hearing from the young American expert upstairs [actually, I was not upstairs at all, but in the same office as Bob Parrish, Watson, Crick and Peter] that the textbook was probably wrong, or out of rumors about what Pauling was thinking — relayed by his son Peter at Cambridge". Lear (p.195) goes considerably further in stating that Watson "discloses how he used his young friend Peter Pauling to spy on Pauling's brilliant father, Linus". And Lwoff (p.227) observes that "Peter Pauling works in the Cavendish, receives detailed letters from Pasadena and informs his colleagues of the evolution of his father's work".

On careful reading of *The Double Helix* we find that Watson says nothing of the sort. Consult, if you will, the name index for the citations to verify this, and come to the conclusion that these statements and innuendoes in the reviews are pure fiction. So much for spies!

● *The Myth of the Race.* Another

thread, nay, hawser, which twines through the reviews, is the "breathless race" between Watson and Crick on the one hand, and Linus Pauling on the other, towards that legendary ceremony, established by the dynamite tycoon, in the gloomy, sunless Stockholm of December. The same strand snakes its way through *The Double Helix*. How, though, can there be a race with only one team and no antagonist? At this stage (1952–1953), Pauling, whose reputation as a scientist was unequalled, had well over 200 publications under his belt, including a dozen or more books universally appreciated and widely read. His ticket to Sweden was long overdue. (He did, in fact, make this journey the very next year in 1954 to collect his first Nobel prize.) Was he racing Watson? Certainly not. To Pauling, in Peter's view (*New Scientist*, May 31 1973, p.558), DNA was just another chemical, intrinsically equal in interest to, say, sodium chloride; both presented interesting structural problems, so why race with DNA?

● *The Myth of the Filched Photographs and the Dipped Data.* The fourth and final myth concerns the X-ray data, and whether Watson and Crick came by them by unorthodox methods. Among the reviewers we find Sinsheimer referring to "cadged data" and a "privileged report", Lear to a "clandestine communication channel" and supposedly "confidential data", and Merton to "an odd expedient for gaining access to badly needed information". Lwoff and Chargaff (in his review, not included in this volume) quote a crucial paragraph from *The Double Helix* which led to both of them to comment on ethics. The same passage is reproduced by Perutz, the supposedly clandestine channel, in his letter, pp.207–210, in which, as well in the letters by Wilkins and Watson which follow, it is made abundantly clear that the report was not confidential, and the data had already been

disclosed in open seminars.

As a matter of fact, an X-ray diffraction photograph which, although not of the high quality of those produced by the two groups at King's, clearly shows the characteristic helical pattern of the B structure, had been published by Astbury years earlier, so all the fuss over stolen data was really unnecessary.

Five of the reviews of *The Double Helix* included here were previously reviewed by Gunther Stent, the editor. The article by Chargaff, that *vieux terrible* of the DNA saga, although not reprinted because he withheld permission, is reviewed. (Anyone wishing to read the original will find it in *Science* 29 March 1968; p.1448). Of the seven new reviews, one of them warrants comment, that by the bipseudonymous "F.X.S.", originally "F.R.S.". This is not a review at all, but verbal virtuosity by a polylingual sesquipedalianist, and why Stent chose to include it is an enigma, as it adds little insight into DNA or those connected with it. F.X.S. is coy about his identity, but really, who cares? His piece is worth reading, but hardly reprinting.

There are numerous other important reviews not included by Stent — by Lord Todd in *Chemistry in Britain*, Sokolov in *Newsweek*, Bernstein in *The New Yorker*, Maddox in *Nature* and so forth. Another not selected by Stent, by J. Field, appeared in the *Journal of Irreproducible Results*, (Vol.17, December 1968, p.53). Because it expresses as well as anything the flavour of Watson's book, it is reproduced above (with the permission of the editor).

Anyone who hasn't yet read *The Double Helix* should certainly do so, but, even if you own a copy, the additional material in the present volume amply justifies its purchase. □

Jerry Donohue is Rhodes-Thompson Professor of Chemistry at the University of Pennsylvania. He spent the academic year 1952–1953 as a Guggenheim Fellow at the Cavendish Laboratory, University of Cambridge.

Schumacher reconsidered

Eric Ashby

Small is Possible. By George McRobie. Pp.331. ISBN hbk 0-224-01858-2; ISBN pbk 0-06-090694-4. (Jonathan Cape/Harper & Row: 1981.) Hbk £7.95; pbk \$5.95.

THERE is a mysterious jackpot logic about best-selling books on the environment. Why has Vogt's *Road to Survival* sunk without trace while Leopold's *Sand County Almanac* is quoted and requoted? Both were published a generation ago; both are elegantly written. Why is Thoreau, who liked his wilderness to be as tame as a tabby cat, still regarded as a conservationist's guru? And why is Schumacher's *Small is Beautiful* treated as a seminal tract in self-sufficiency? Surely Tolstoy had similar ideas and there were Tolstoyan communities (well described by W.H.G. Armytage in *Heavens Below*, published 20 years ago) in Britain in the 1890s.

Small is Beautiful, I'm told, still sells well, thanks (ironically) to the large-scale techniques of book production and marketing. It is seductively written and full of wisdom. But wisdom, alas! is only a minor ingredient in practical politics. As devotional reading, Schumacher's book is still popular; but as a blueprint for a new economic policy in the manifesto of a political party (except, perhaps, the misnamed ecology party) it's not a starter. Not only in the capitalist world but in the communist world too, small may well be beautiful, but it is the giant enterprise that provides energy, packaged foods in the supermarket, communications, transport, the dish-washer in the kitchen and the car in the garage. The communes in China are an exception to this generalization, but will they survive as China becomes a great industrial power? For Britain, at any rate, it does not seem unduly cynical to assume that if a choice had to be made at the polls between an economic life style which was, in Schumacher's sense, beautiful, and one which gave the greatest material comfort to the greatest number of people, then beauty would lose out.

So the stock comment on *Small is Beautiful* is "beautiful, no doubt; practicable, no". Therefore when a sequel appears with the title *Small is Possible*, it should be accepted as a challenge to re-examine Schumacher's thesis. It is in that spirit that I read the book.

George McRobie, the author, was Schumacher's assistant and co-founder of the Intermediate Technology Development Group, ITDG (one of the many — far too many — acronyms in the book). He does not pretend to write with the felicity of Schumacher but he doggedly assembles evidence to validate the book's title. The book is, for the most part, an annotated catalogue of enterprises in intermediate or

"appropriate" technology which are consistent with Schumacher's thesis, namely that conventional capital-intensive projects are a disaster in Third World countries and may well be the signpost toward disaster in industrialized countries; and — this is the message of the book — that there are alternative small people-intensive projects which are viable. McRobie gives a list, with addresses, of nearly 100 organizations concerned with appropriate technology engaged in hundreds of little experiments. The evidence persuades me (at any rate) that there is a minority movement to reject the life-style of what used to be called the military-industrial-complex; not on political grounds but on what may become a much firmer foundation: moral grounds. It is no more than a sprinkling of enthusiasts (some of them cranks) in the interstices between super-highways, power stations, acres of petrochemical works and refineries; uncoordinated, fragmented. But something interesting is going on, and if the fragments coalesce a new life style might emerge.

The late E.F. Schumacher, prophet of self-sufficiency.

What is going on? Here are a few samples taken from McRobie's book.

He deals first with the most urgent and relevant application of Schumacher's thesis: the design of equipment for agriculture and industry in Third World countries. The principle is simple. In countries with surplus manpower, and without technical sophistication, capital investment per worker has to be as low as possible. When a British trade mission went to Nigeria, Schumacher's group (ITDG) put into their hands a stencilled *Guide to Small-scale Equipment for Rural Development*, "of animal and man-operated agricultural equipment obtainable from little hole-and-corner firms in Britain". Not at all what the mission intended to propagate in Nigeria; but (said Schumacher) "This thing was torn out of

their hands by people who said: For the first time you bring us something of interest, instead of the usual glossy catalogues". That was 15 years ago. Since then the ITDG has had an impressive record of service to Third World countries. A building panel set up, in five African countries, units for making bricks at a capital cost of £400 per workplace, compared with £40,000 per workplace in a large modern brickworks; and it invented and put into production a fibre-reinforced cement for roofing at a fraction of the cost of the normal commercial product. A water group published handbooks on the making of pumps, wells and low-cost irrigation systems. A farming group has designed and put into production (in Zambia and Nigeria) workshops for making machines for weed-control, groundnut harvesting and fibre stripping. A transport unit based on the Engineering Department at Oxford has designed the Oxtrike: a cycle rickshaw which can be made in Third World countries. Windmills in Ethiopia, water pumps in Nepal, mini-hydro generators — all locally made — replace the imported equipment which cannot be kept in good repair without skilled technicians. And — most imaginative of all — the Rural Health Panel has, under the skilled guidance of Dr Katherine Elliott, promoted the training of auxiliaries in health care, in collaboration with the World Health Organization.

These efforts may seem to be trivial crumbs to offer the Third World when set beside the massive expenditures on steel mills for India or on the Volta Dam for Ghana; too trivial for all the effort involved. But they have an importance which cannot be quantified: they may, with luck, convince the Third World that it does not want to ape Europe and America in its patterns of society. And it may help to repair some of the damage we have done in exporting the wrong kinds of goods and education to the Third World. Thus, when we exported medical education to the university colleges of tropical Africa we arranged (with the noblest of motives) that its quality and content would be indistinguishable from that in a London medical school. The surgical staff, training doctors skilled to remove the gallstones of cabinet ministers in the capital city, regarded with impatience the activities of an African professor of social medicine, who put his efforts into the holding of competitions in the villages for the construction of earth closets. Anyone who dared to suggest that the prime need was for medical auxiliaries (as the Soviet Union and China had) was scarified with criticism. The universities were suspicious of any subject in the curriculum which would not have been appropriate in London. One encouraging message in McRobie's book is that this technological snobbery is diminishing. African universities are becoming relevant to African problems. Countries where Small has been

Practicable (if not Beautiful) for millennia may still have a chance to escape some of the social perils of modern technology.

What about the industrial West, where the proudest boast of technologists is that they save manpower at the cost of capital investment per workplace? It would be stupid to dismiss the enormous social benefits of mass production. For every one man whose life is dissipated on a production line in British Leyland there must be hundreds of families whose lives have been liberated by the possession of a car. Holidays, picnics, visits to friends and relations, life in a suburb and a short drive to the office: all these are incomparably easier to secure than they were for the so-called lower classes when I was a boy. While there was full employment, and material progress brought with it some improvement in the quality of life, the achievements of the industrial West were welcomed. For the first generation owner of a car and a refrigerator and an air ticket to Majorca, the warnings of Schumacher were dismissed as neurotic.

It is a different story today. Thanks to education and the media, the unemployed are more articulate than they were in the 1930s. They do not equate unemployment with leisure, even though they are paid to be unemployed. To be without work is as dangerous as to be without love. So, suddenly, the application of Schumacher's ideas (and not just Schumacher's: they are the ideas of William Morris and Tolstoy in modern dress) becomes relevant and politically important. McRobie describes how hundreds of small groups of people in America, Canada and (on a smaller scale) in Britain have detached themselves from the conventional pattern of society, to seek a pattern which does not have the formula "economies of scale" woven into the design. In America some of the experiments have official support. There is a National Center for Appropriate Technology, inspired by Senator Mike Mansfield. There is the California Office of Appropriate Technology, started by order from Governor Jerry Brown, with a budget of \$900,000, encouraging the use of solar energy, and designing small-scale sewage systems and techniques for aquaculture. In the Bronx, some of which is a waste of derelict city lots, an Institute for Local Self Reliance has mobilized local labour to cultivate gardens and rehabilitate decayed property. And in Canada — in many ways the most enlightened of Western nations — there is in the ugly mining town of Sudbury a project called "Sudbury 2001" which, with a provincial government grant of \$600,000, is preparing some of the workforce for the inevitable redundancies they see ahead.

McRobie's chapter on the "alternatives" movement in Britain is less encouraging. It seems (perhaps there is another side to the story) that neither governments nor trade unions have taken much interest in the possibilities of small

collectives. The experiences of the Kirkby Manufacturing and Engineering Ltd (KME) and the *Scottish Daily News* do not generate much confidence. Of course it is sheer fantasy to imagine that ICI, BP and the Central Electricity Generating Board will dissolve in a flood of little collectives making their own paints, heating their farms with home-made methane, using windmills knocked together by the local blacksmith. But the unemployed displaced

by a combination of world diseconomy and new technology are going to demand work. If they do not get work, society as we know it may be shattered. If we have to invent work not to produce things for profit but to satisfy a deep genetically coded human need, then perhaps Schumacher's ideas are worth another thought. □

Science fiction as Marxism

James Gorman

Robert A. Heinlein: America as Science Fiction. By H. Bruce Franklin. Pp.232. ISBN hbk 0-1950-2746-9; ISBN pbk 0-1950-2747-7. (Oxford University Press: 1981.) Hbk \$18.95, £10; pbk \$4.95, £3.95.

READING H. Bruce Franklin on Robert Heinlein is a bit like reading an analysis of a sexual farce by a stiff-necked, bible-bound fundamentalist who can never get his mind off the fact that sex is, after all, sinful. Franklin has produced a painstakingly detailed Marxist analysis of what, at its best, is flashy escapist fiction. Heinlein's heroes, his cynicism and sentimentalism, his taste for adventure, all his tales of space exploration, war, sexual fantasy, time travel and immortality become a rather dreary reflection of the contradictions of capitalism in the United States.

Franklin leaves the science in the fiction more or less alone; this omission does no disservice to Heinlein. Science only provides him with the authority by which reality is breached — it is the excuse for the reader to believe in the fantasy. When it suits his purpose, Heinlein is not averse to using magic in its place.

Heinlein is at least as fond of social theory as he is of science, and his books are full of expostulation on one half-baked political philosophy or another. And, as Franklin points out, he does reflect his times. In the 1950s he produced anti-communist novels; in the 1970s he explored narcissistic sexual excess in some of the worst writing of his career. And, in 1961, at the beginning of one of America's most notorious decades, he produced what is probably his most popular book, *Stranger in a Strange Land*. In it a young human being, raised on Mars, by Martians, comes to Earth, views us all through alien, though human eyes, and finally finds a religion that is part universal sexual love, part hucksterism, part anarchism and part violent elitism. The gentle, loving hero is in the habit of making his enemies, and other undesirables, disappear by a wink of the mind, a trick he learned on Mars.

This is, indeed, very close to "America as Science Fiction". But when Franklin presses his point to argue that the hero "embodies our most infantile fantasies and

the central goal of bourgeois ideology — the unfettered freedom of the individual will", he is less convincing. Indeed, when, throughout the book, he holds up Heinlein as a mirror that reflects the nature of capitalist society, he undermines his case by two unfortunate omissions — he leaves out Heinlein, and he makes his analysis on the basis of unargued and undemonstrated assumptions.

Where indeed is Heinlein in all of this? Franklin gives us only a thumbnail biography, which concentrates more on the economic conditions in the country when the author grew up than it does on Heinlein himself. And where is Heinlein's imagination, his writing skill, his ability to create compelling stories? A writer of fiction is less a mirror than a lens, that refracts rather than reflects the light of his culture, bending it with his own idiosyncrasies. In Franklin's formula the curve of Heinlein's lens is missing.

Also missing is some back-up for his ready-made Marxism. It may well be true, as he notes in passing, that the conditions of the two main groups of workers in America before World War II were "the debt peonage characteristic of the majority of Black rural workers and the wage slavery of mine and factory labor", and that "class struggle . . . has constituted actual human history", but his case would be stronger if he demonstrated his points rather than asserting them. Nor are these isolated examples. He tells us, for instance, that "If the will is free to do anything it wishes, the will is free from the apparent laws of the physical universe and also free from the apparent laws of human social development". He doesn't tell us what either set of laws are, perhaps assuming that the precepts of dialectical materialism are as well known and widely accepted as gravity.

What Franklin's book could use, finally, is a bit more of an internal dialectic. If we were to see the clash of culture and individual in Heinlein's work, we might come away with a richer understanding of the author, and of America. □

Spring Books

Gel Electrophoresis of Proteins: a practical approach

Edited by D. Rickwood and B. Hames

A laboratory aid for all those wishing to separate proteins by gel electrophoresis. Contains detailed recipes and step-by-step instructions on the procedures involved in all the different types of electrophoretic separation.

0 904 147 22 3 (soft) £7.50/US \$18.00
300 pp (approx.)

Rapid and Automated Methods in Microbiology and Immunology: a bibliography 1976-1980

A unique reference tool to help you find the simplest method or technique best-suited for your laboratory. Contains over 3000 citations on practically all the rapid and automated techniques introduced in the field during the last five years.

0 904 147 19 3 (soft) £15.00/US \$36.00
200 pp (approx.)

Tooth Surface Interactions and Preventive Dentistry

Edited by G. Rolla, T. Sonju and G. Embery

Proceedings of a workshop held December 1980 in Oslo and part of a series devoted to current aspects of dental research concerned with the interactions occurring at the tooth surface. Particular emphasis is directed at the role of inorganic ions, especially stannous fluoride, in influencing the metabolism of oral bacteria and their adherence properties.

Colourful tale of two Voyagers

J. Veverka

Voyage to Jupiter. By David Morrison and Jane Samz. Pp.199. (National Aeronautics and Space Administration: 1980.) Pbk \$7.50 US only.

NASA-sponsored books describing flight missions to various planets are not hard to find. Unfortunately, good ones are as scarce as impact craters on the surface of Io. Typically, such books amount to little more than collections of pictures intermingled with spacecraft details and other mission minutiae. Science gets mentioned only in passing and at so superficial a level that even the casual reader feels short-changed.

Voyage to Jupiter is not such a book. It is a beautifully illustrated, vivid account of the two historic Voyager encounters with Jupiter in 1979, as well as a factual summary of the initial scientific results. Everyone should find it interesting; even the sophisticated reader will find it informative.

In part, the successful outcome may result from the combination of talents of the two authors: Samz, a science writer, and Morrison, a planetary scientist and a member of the Voyager Imaging Team who was personally involved in many of the discoveries described in this book. Certainly, this volume does contain details of the spacecraft construction, the mission profile and the requisite pictures of the major participants, but interwoven with all this is real, substantial science. Voyager's many discoveries — rings, volcanoes, lightning, new satellites and so on — are not merely catalogued chronologically, but are tied into a comprehensive new picture of Jupiter and its satellites. Without question, *Voyage to Jupiter* is more than a NASA picture book, but it is certainly that too. The Voyagers are the first planetary spacecraft to have sent back large quantities of true colour data, and it would be difficult to imagine a better subject for colour imaging than the jovian system. Many of the best of these pictures are reproduced admirably in this volume.

The book opens with a pair of chapters summarizing our pre-Voyager knowledge of the Jupiter system based on three centuries of telescopic observations and the initial reconnaissance by Pioneers 10 and 11 in 1973-1974. Next, the authors discuss the spacecraft, the scientific work that its eleven instruments were designed to carry out and some of the individuals responsible for these experiments. Then come three chapters giving a day-by-day account of the two encounters. Here the reader can share some of the excitement experienced by those who were fortunate enough to be in Pasadena during these two historic events when major discoveries were being made almost hourly. Two of the remaining three chapters aptly summarize our

current, post-Voyager, view of the planet and its satellites, and the volume ends with a discussion of future missions to Jupiter. Sadly, this chapter must be very short. At present, the only mission planned is NASA's Project Galileo, which will investigate the jovian system in the latter half of this decade. For a while at least, our view of Jupiter and its satellites will remain that relayed to us by Voyager in 1979.

Voyage to Jupiter — an excellent little book — sets a high standard for future NASA publications of this sort. In these days of \$30-\$40 science books, it is an absolute bargain which I heartily recommend. □

J. Veverka is at the Laboratory for Planetary Studies, Cornell University, New York.

Here comes Halley

David W. Hughes

The Comet is Coming! The Feverish Legacy of Mr Halley. By Nigel Calder. Pp.160. ISBN 0-563-17859-0. (BBC: 1980.) £8.75. To be published in the USA by Viking, \$12.95.

"EVERY seventy-six years or so Halley's comet punctuates history like an exclamation mark in the sky". It was last seen in 1910 and it is due back soon. To be precise it will be at perihelion, the point in its orbit closest to the Sun, on 9 February 1986. The preparation for this momentous event has already started. The European Space Agency is busily organizing the Giotto spacecraft which will pass as close as possible to the cometary nucleus. The International Halley Watch is being supervised by the Jet Propulsion Laboratory in Pasadena and this will co-ordinate all the ground-based and near-space observations of the comet. The public are getting ready

Edmund Halley, Astronomer Royal from 1720 to 1742.

Hulton Picture Library

too. Brian Marsden once said "To the man in the street the Solar System consists of Mars, the rings of Saturn and Halley's comet". Comets fascinate people and the next few years will see a flood of books, television programmes and newspaper articles on the subject.

Nigel Calder and the BBC are in the vanguard and *The Comet is Coming!* is the book of the television programme that is to be shown first on BBC2 in mid-1981. The book is excellent. Calder has a beautiful turn of phrase and often had me chuckling. The text is non-mathematical and infectious readability. The illustrations have been carefully selected and many are new to me — not for Calder is the regurgitation of the old faithful. The style is journalistic but you are never left in doubt that the author is a sensible scientist.

Portent of a new King? Detail from the Bayeux tapestry showing the appearance of Halley's comet.

Halley's comet and its like are ostentatious and elusive and because of this they create a no-man's-land of speculation where crazy ideas may be fantasies or brilliant insights. This book is a sure guide to this no-man's-land and underlines the joys, mysteries and frustrations of cometary science. We read of the attitude of the superstitious who regard comets as telegrams from the Gods — disorders in heaven importing changes of times and states. The role of Edmund Halley is stressed, especially his work on orbits. The physical and chemical nature of comets and the suggestions as to their origin are reviewed, as are the problems of cometary discovery and observation. Fred Hoyle and Chandra Wickramasinghe's theory that comets could have brought life to Earth and are even today scattering disease over the globe through the influx of dust is discussed. Calder examines the consequences of a collision between the Earth and a comet; and special reference is obviously given to the demise of the dinosaurs about 65 million years ago!

The book is well referenced, well indexed and I recommend it strongly. □

David W. Hughes is a Lecturer in Physics and Astronomy at the University of Sheffield.

Star-spangled dream

Brian O'Leary

Bound For the Stars. By Saul J. Adelman and Benjamin Adelman. Pp.335. ISBN hbk 0-13-080390-1; ISBN pbk 0-13-080382-0. (Prentice-Hall: 1981.) Hbk \$17.95, £11.65; pbk \$8.95, £5.80.

"WE ARE too great a nation to limit ourselves to small dreams" said President Reagan in his inaugural address. Amongst the budget slashing that has followed, it is difficult to imagine just what dreams Mr Reagan has in mind.

One thing is clear: there is no shortage of big dreams in space. Sound engineering concepts wait for their political and commercial opportunity. Once they are triggered, we can expect to witness an explosive renaissance in the high frontier. The question is not whether it will or should happen; it is when, how and by whom. Soviet-American political and military pressures mean we are in space to stay.

Different writers, however, have different goals. Gerard K. O'Neill, in *The High Frontier*, argues the case for satellite solar power stations and space habitats manufactured in space from lunar materials. Carl Sagan, in *Cosmos*, describes the excitement in expanding scientific programmes in modern astronomy, the search for extraterrestrial intelligence and unmanned planetary exploration. In *The Fertile Stars*, I show how asteroid mining and retrieval could provide the key to expanding the limits to growth of the world supply of energy, food and raw materials, to pave the way to space colonies and manned planetary exploration. Saul and Benjamin Adelman have a rather less accessible dream to offer; *Bound for the Stars* champions interstellar travel as the primary goal for future space activity.

There is little question that NASA's lack of a well-defined objective has hurt the American space program immensely. The lunar-landing commitment made by President Kennedy in 1961 (and completed eight short years later) was the last grand goal of space. We are now seeing the final vestiges of Apollo momentum petering out — the Voyager Saturn fly-bys will be the last American planetary probes to return new data for at least another five years.

Apart from the space shuttle, the US civilian space programme is virtually dead, while the Soviets, Europeans and Japanese move steadily forward. For example, all three plan a Halley's comet mission during its once-in-a-lifetime appearance in 1985 and 1986; budget cuts have grounded an American Halley probe. The Adelmans say these retrenchments can be ascribed to shortsighted year-to-year planning in the US federal government, and contrast this with the project-approval system of the European Space Agency. They stress the importance of changing NASA's charter to protect it from the lack of continuity it

suffers from the annual budget cycle.

The best feature of the book is its wealth of detail on concepts of interplanetary and interstellar travel. The authors trace the history of the development of propulsion systems and navigational techniques with skill and perceptiveness. Most of the concepts have not flown. They describe, for example, the ill-fated Orion Project (in which exploding atomic bombs propel a large spaceship) as a "science orphan no one wanted to adopt".

The Adelmans' stand that interstellar travel should be the basic unifying aim for future space activity is controversial. Because starships are well beyond our current technological capability, many decision-makers will not accept such a heady goal. By contrast, Apollo was — and manned Mars landings, asteroid mining, space industrialization, space colonies and satellite solar power are — feasible projects which could use today's technology.

The first few chapters of the book are a smorgasbord of what appear to be afterthoughts. The authors skip rapidly from the origin of life to the search for extraterrestrial intelligence to a survey of the Solar System, back to life in space, plans for biological experiments aboard Spacelab, controlled ecologies, Solar System travel, space colonies and so forth.

These sections are weak, covering the subjects incoherently with misleading and biased remarks: for example, the belief that all life must be carbon-based and depend on water (see *Life Beyond Earth* by Gerald Feinberg and Robert Shapiro for a different view); "Dr Carl Sagan of Cornell University believes that about a million civilizations exist in the Galaxy on the same or more advanced level than Earth civilization" (p.17, too strong); "The galactic cosmic rays from outside the solar system are not a serious hazard, even for voyages lasting more than a year" (p.41, not true). In addition, they show a strong bias against satellite solar power and for nuclear power (pp.80–85) which, in the United States, might prove politically unacceptable.

The real strength of the book, then, is in its thorough discussion of the prospects of interstellar travel. I have been looking for a handy reference on the subject, and this is most certainly the best available. I applaud the Adelmans' remarks about the importance of keeping the space programme alive and that we need a goal to work toward.

I believe political and military pressures are the foot in the door, economics will become the driver (space industrialization) and the thorough exploration of the Universe will be the ultimate and most fulfilling by-product.

In spite of all the budget-cutting and pessimism, we have some ideas. The Adelmans' treatment of interstellar travel in this new book is one of them. □

Brian O'Leary is a former scientist-astronaut, and author of *The Fertile Stars*, to be published in June.

The pluviiculturists

Richard W. Katz

The Rainmakers: American "Pluvi-culture" to World War II. By Clark C. Spence. Pp.185 ISBN 0-8032-4117-8. (University of Nebraska Press: 1980.) \$15.95, £9.60.

In 1930, "Dr" George Ambrosius Immanuel Morrison Sykes was employed by the Westchester Racing Association to ensure sunny weather at Belmont Park racetrack in New York City. Although not a meteorologist, Sykes called himself a "meteorologist", that is, someone who can actually control the weather. Besides suppressing rainfall, Sykes' Weather Control Bureau also claimed to be able to prevent snow, hail, frost and hot weather. The Bureau could, on the other hand, generate rainfall if so desired. To perform these seemingly impossible feats, Sykes relied upon a bizarre assortment of equipment, ranging from a toy propeller to a tub of smelly chemicals. His efforts to guarantee sunshine at Belmont Park, needless to say, met with only mixed success.

Although the putative beginning of scientific weather modification dates from 1946, with Vincent Schaefer's successful seeding of clouds using dry ice, Clark Spence's entertaining book describes the largely forgotten history of earlier, less-scientific rainmaking attempts in America. David Jordan coined the term "pluvi-culture" to refer to the endless rainmaking schemes that were inevitably proposed upon the occurrence of drought. Most of these "pluviiculturists" were not nearly as outlandish as "Dr" Sykes. They included James Espy, a true scientist, whose theories concerning a relationship between fire and rainfall were respected by the scientific community. The most popular rainmaker was probably Charles Hatfield (the "miracle man"), a former sewing machine salesman, who used the "smell maker" technique involving the release of chemicals into the atmosphere. Reputedly responsible for the great flood of 1916 in San Diego ("Hatfield's flood"), he has become a part of the folklore of southern California.

The recipe for success as a rainmaker was simple. Above all, it required being a convincing salesman to take advantage of the public's gullibility. When faced with drought, farmers were desperate and

willing to try almost anything. This "drought psychology" made the "no rain, no pay" schemes offered by the rainmakers highly attractive. Aided by weather forecasts and information on local meteorological patterns, the pluviiculturists depended on occasional coincidences with the occurrence of natural precipitation to demonstrate the viability of their rainmaking operations. Plausible excuses could always be dreamed up in case of failure. Sensationalized journalism helped too, publicizing apparent successes, while not bothering to mention failures. The scientific community, including the US Weather Bureau, remained steadfast in opposition to nearly every rainmaking scheme, but to no avail; scientific expertise was no match for expert salesmanship.

The rainmakers took advantage of several common fallacies, all somewhat statistical in nature. The *post hoc, ergo propter hoc* fallacy arose in connection with the coincidence between rainmaking operations and subsequent rainfall. Pluviiculturists always took credit for any rainfall, even if it occurred several days after their operations or only at distant locations. Another fallacy concerned the often misused "law of averages". Rainmakers were well aware of the odds for rain, correctly realizing that it was sure

to occur eventually. That the public was confused about the law of the averages is no wonder; even Spence is apparently confused about it. He suggests that the task of a rainmaker was made easier, because an extended drought increased the likelihood for rain.

It is impossible to read Spence's book without being compelled to make comparisons with more recent weather modification activities. Some striking similarities are present. Overstatement continues to be employed to sell rainmaking, with one current euphemism for such activities being "weather resources management". Journalists' reporting of the subject remains somewhat misleading or inaccurate, and the public tends to accept the same fallacious reasoning. As always, interest in pluviiculture is revived whenever a drought occurs. To justify government funding of weather modification programmes, politicians rely to some extent on the same "it's worth a try" or "it can't hurt" arguments. If Spence's history of American rainmaking were extended to the present, how different would it be? □

Richard W. Katz is in the Department of Atmospheric Sciences at Oregon State University, Corvallis.

Two psychology textbooks recently reviewed in *Nature* (289, 710; 1981), *Behavioral Neuroscience* (by C. W. Cotman and J. L. McGaugh) and *Physiological Psychology* (by T. S. Brown and P. M. Wallace), are available in the UK in a cheaper international edition. Both are published by Academic Press, and the prices of the international editions are £6.25 and £6.40, respectively.

Richard of York's battles not in vain . . .

Ann Henderson-Sellers

Rainbows, Halos, and Glories. By Robert Greenler. Pp.240. ISBN 0-521-23605-3. (Cambridge University Press: 1981.) £15, \$24.95.

ACCURATE recollection of the ordered colours of the rainbow by means of the nursery sentence, "Richard Of York Gave Battle In Vain", is a necessary but insufficient basis for understanding in the eyes of Robert Greenler. He wants us also to be moved to wonder at the mysteries of optical phenomena in the sky. His book is reminiscent of a fascinating, extended tutorial with a professor of physics who, fortunately, combines hard scientific research with an almost childlike delight in beautiful things. During his discourse we are prompted to exclaim at magnificence, explain apparent enigmas and reinterpret historical events through computer simulations of atmospheric optics.

The book divides into three sections dealing with rainbows and ice-crystal optics, and then simulation and understanding of historical and modern sky displays, before finally returning to colourful mysteries, myths and mirages. Throughout, facts and frustrations are, like the individual rainbow we each view, enriched by Greenler's personal experiences. For instance, he illustrates the concept of the constant angular size of rainbows by a description of his doomed attempts to photograph the, apparently, miniature bow formed in the spray of his garden hose. The author is clearly "hooked" on his subject; he admits to seeing and searching for rainbows everywhere and has even captured infrared bows on film.

Despite his obvious love of rainbows it is with the optical displays formed by ice-crystals that Greenler is most strongly associated. As a physicist who has spent extended periods in Antarctica and the Arctic his fascination with this topic is understandable, but it is frustrating to realize that many of the sky effects he illustrates in this section are seen only rarely in more populated regions. This is because the huge variety of optical effects discussed depend upon the presence of simple hexagonal ice-crystals while most of us see our ice-crystals as snowflakes. This pinpoints the only real criticism that I can make of the book: it is not focused on a specific readership. As a meteorologist I am frustrated by the fact that the weather which, after all, is creating most of these effects, is mostly ignored. This is a pity because it makes an otherwise outstanding book tricky to use directly in taught courses. Despite the fact that the book is not intended as a textbook, with little additional effort topics could have been related to other disciplines. For instance, the very thin cirrostratus clouds

responsible for the 22° halo, itself generally considered as a forerunner of stormy weather, could also be considered to be a sky phenomenon. I can testify to having used halo occurrence to convince a non-meteorologist that a blue sky could be totally cloud-covered. Despite these reservations I was drawn on by the enthusiasm of the writing. Indeed, I spent some time testing the author's assertion that hexagonal ice-crystals have preferred orientations in the atmosphere, to the extent of spinning and dropping computer cards around my office.

With a flair for detective work which Holmes would have envied, Greenler considers his computer simulation of the famous "Arcs of Lowitz". These composed part of the historic sky display seen and sketched by Tobias Lowitz in St Petersburg in 1790. The accuracy of the simulated curves seems remarkable but Greenler remained dissatisfied. By returning to the written description he has demonstrated that the sketch is not a "snapshot" but a composition of a number of hours of viewing. This revelation solves the outstanding problems

which depended upon knowledge of the solar zenith angle.

The final 50 pages are devoted to colourful optical phenomena in both senses of the word. We are treated to pictures, and explanations, of white and black clouds in the same scene and then yellow, green, blue and red clouds. Such comparatively "every-day" sights pale before the "Specter of the Brocken". This apparition takes the form of a misty giant around whose head are a series of brilliant halos. Many air travellers have seen the same effect, a glory, which simply requires the observer to be in direct sunlight with his anti-solar point projected onto a cloud.

In the opening pages of the book the author states, "I have chosen, knowingly to include myself . . . my delight at seeing . . . my excitement in the process of discovery". Despite my slight unease at such an apparently selfish exercise I shall use and recommend the text. Like the Pied Piper of Hamelin in his rainbow-coloured coat, Greenler charmed me into following and will, I am sure, similarly entrap other readers. It appears that the white rose of the house of York was not lost in vain. □

Ann Henderson-Sellers is a Lecturer in Meteorology at the University of Liverpool, currently studying global climate at the Goddard Institute for Space Studies, New York.

Evidence of intent

John Stachel

The Greatest Power on Earth: The Story of Nuclear Fission. By Ronald W. Clark. Pp.342. ISBN 0-283-98715-4. (Sidgwick & Jackson: 1980.) £8.95. To be published in the USA by Harper & Row, \$13.95.

SHORTLY after the accident at Three Mile Island, a Japanese journalist visited a centre for evacuees from the vicinity of the reactor. As startling as the accident itself was the fact that a reference to Hiroshima drew a blank from those he interviewed; none of them recognized the name. Such ignorance in itself justifies more books on the story of the atomic bomb, which is basically the topic of Clark's book.

Over two-thirds is devoted to the story, from the discovery of atomic fission in late 1938, through the wartime efforts to develop nuclear weapons in Britain, the United States, Germany and Russia, up to the explosion of the first Russian bomb in 1949. A 40-page prologue to the book attempts a potted history of nuclear physics; while the last 40 pages wind up the story with brief accounts of the development of the fusion or hydrogen bomb, the attempts to use fission as an energy source and the growing awareness of radiation perils associated with peaceful and military uses of nuclear power.

The prologue is not too successful. It betrays a shaky acquaintance with the

scientific literature, resulting in numerous small errors and confusions. The placement of emphasis, too, is sometimes curious.

The core of the book demonstrates a wide acquaintance with the atomic bomb literature, both original documents (including some discussed in print for the first time) and later memoirs and analyses. On the whole, it seems a thorough and reliable account, correctly giving greater emphasis to work done in Britain than many American sources. This portion of the book commends itself to those in search of a readable, fairly non-technical account of the scientific, diplomatic and military events leading up to the "Birth of the Bomb" (to use the title of Clark's previous account of Britain's underrated contribution to the early phases of the story). Those in search of a deeper analysis of the potential background to the decision to drop the two bombs on Japan are still advised to consult Martin Sherwin's *A World Destroyed* (Knopf, 1975).

The frequent use of hyperbole is annoying: "In 1905 Einstein erupted into a surprised world" (elsewhere "an astounded scientific world" receives Einstein's 1905 relativity paper); Russian nuclear research is interrupted in 1941 because "German tanks with muffled treads moved through the darkness across the Russian frontier", and so on. There are also a few curious phrases: "The predominance of Jewish nuclear physicists on the Continent — in strong contrast to the situation in Britain —

has long been a subject for discussion"; by whom one wonders?

But the more serious problems of the book begin with its title. It is basically the story of nuclear fission, as its subtitle indicates, yet the title clearly refers to nuclear fusion — a reference reinforced by the exploding hydrogen bomb on the jacket cover. Careful reading of the text makes clear the distinction between fission and fusion, but hasty readers may be left confused.

More important is the question of the distribution of emphasis inherent in the structure of the book. Surely, the critical element in our current nuclear predicament is the combination of the fusion or hydrogen bomb, with its capacity for unlimited growth in explosive power, and a missile technology capable of accurately placing such bombs on target within minutes of launching. But no sense of the crucial nature of this development emerges from the brief concluding section of the book. Indeed, what is the moral of Clark's story? He says all the "right" things about the perils of nuclear weapons, and dangers of nuclear radiation — except for one sentence in his concluding paragraph, which plays into the hands of those currently trying to prepare the public for "limited" nuclear wars. He says,

It would be tragic if a limited nuclear exchange, halted after each side had experienced the agony of one city put to the bomb, were necessary to bring men to their senses and to realize, at last, that there are no victors in nuclear war.

Not only would it be tragic (reminding one of the man being led to his execution who assures the audience that this will certainly teach him a lesson!); it is so unrealistic a prospect, as Lord Mountbatten came to realize, that its contemplation as a pedagogical device seems irresponsible.

Finally, there is the broader question raised by the context in which Clark's account places the story of nuclear weapons. Focusing attention in the opening sections exclusively on the development of nuclear physics fosters the all too prevalent view of science and technology as independently evolving structures. For more direct evidence of this outlook, one need look no further than the opening sentence of Lord Zuckerman's preface:

The keystones of our century's history are those scientific and technological advances — radio, the internal combustion engine, antibiotics — which have determined the pattern of life which half the world now leads, and for which the other half strives . . .

or the opening paragraphs of Clark's first chapter. After evoking the political and social turmoil of late 1919, inflation and starvation in Central Europe, civil war in Russia, soldier's soviets in Britain, American rejection of the League, Clark continues:

Yet this record of battery and barricade, which added a bloody touch to the first autumn of

peace, was of infinitely less importance to the future of the human race than three events in the worlds of astronomy and physics.

More disturbing than Clark's particular choice of three events (about which more could be said) is the very idea of singling out some group of scientific and technological developments and setting them in apposition to the symptoms of vast social, economic and political upheavals in evaluating their "importance to the future of the human race". I think the evidence exists, in Clark's book and elsewhere, to sustain Raymond Williams' recent judgement:

In the case of nuclear weapons, nothing is more evident than that they were consciously sought and developed, and have continued to be consciously sought and developed. It is true that, as so often in modern technological innovations, much of the basic research had been done for quite other reasons, without foreseeing this particular result. But again as in many other comparable cases, the crucial moment of passage from scientific knowledge to technical invention, and then from technical invention to a systematic technology, depended on conscious selection and investment by an existing social order, for known and foreseen purposes (*New Left Review* 124, Nov-Dec. 1980, p.365).

Until we grasp this element of *intention* in the process of research and development in modern technology, as Williams puts it elsewhere, I fear that efforts to organize movements to control the uses of that technology will be hampered by the feeling that such developments really are inevitable. And in the case of nuclear weapons, I am not certain how much time we have left to learn the lesson. □

More pie in the sky

Paul Davies

Gravity, Black Holes, and the Universe. By Iain Nicolson. Pp.264. ISBN 0-7153-7849-X/0-470-027111-6. (David & Charles/Halsted: 1981.) £10.95, \$24.95.

BOOKS on black holes and the Universe range from postdoctoral research treatises to the wildest distortions of science fiction and the occult. Since the explosion of interest in astronomy in general and black holes in particular, which began during the 1960s, the market has been flooded with literature on matters cosmic. How can the discerning reader tell where to go for both reliable and entertaining treatment?

Having spent many years myself on cosmological and astrophysical research, I do not envy the task of the professional writer who has to attempt to master the technical literature of a difficult and developing subject, and distil out the

features that the scientific community considers to be well established. Still more demanding is the task of grading the various conjectural topics, some of which can be bizarre, into degrees of seriousness.

Take one example: travel through a black hole. Certain solutions of Einstein's field equations display the weird property that they can be continued into regions of space and time that are forever inaccessible to us unless we fall into a black hole. These "other" spacetimes (infinite in number) are sometimes called other universes. Do they exist?

In the sense that certain idealized model spacetimes admit other universes, then the subject is a serious one, and schematic representations of these universes appear in textbooks and mathematical monographs. In spite of this, the models concerned are not supposed to apply to the real world, because they involve certain simplifications (for example, the absence of matter) that manifestly fail in reality. The prevailing opinion is that a more realistic model would not display these other universes, and that an observer who falls into a black hole will not, after all, emerge in a hitherto unknown spacetime, but will crash to oblivion in a region of unlimited tidal stress.

A writer may cover his subject thoroughly yet still miss such subtleties and proclaim that modern physics definitely predicts the existence of other universes. Certainly a glance at a textbook could give that impression. Iain Nicolson is to be congratulated that on this, and many other contentious and delicate issues, he has not only got the facts right, but has conveyed the correct degree of scepticism or reliability appropriate to each conjectural topic.

There is much more to this book than black holes, however. The author takes us gently through Kepler's laws, newtonian mechanics and special relativity, before getting on to the equivalence principle, curved spacetime and the general theory of relativity. He also applies his thoughts to the expanding Universe, and the intriguing topic of its ultimate fate.

The book is nicely illustrated with line drawings and photographs, and has a short bibliography. Although certain advanced topics, such as quantum aspects of black holes, are courageously included (and skilfully handled), the book should still appeal to general readers having only a nodding acquaintance with physics and astronomy.

My initial reaction to this book was to wonder where yet another treatment of this trendy subject could possibly fit in to an already crowded market. The answer is that it is one of the few books that maintains a reliable scientific perspective and a careful treatment, yet covers most of the "fun" topics in detail. □

Paul Davies is Professor of Theoretical Physics at the University of Newcastle upon Tyne.

The diversity of physics revealed

R.H. Dalitz

Encyclopedia of Physics. Edited by Rita G. Lerner and George L. Trigg. Pp.1,157. ISBN 0-201-04313-0. (Addison-Wesley: 1981.) \$99.50, £49.50.

THE publication of a new encyclopaedia of physics is an important event. The subject is growing rapidly, not only in accuracy of measurement and detail of understanding but also in scope. A well organized volume can quickly bring the reader up to date about developments in areas outside his own speciality where new viewpoints and techniques may have become established, and, overall, can significantly speed up the progress of physics itself.

This volume contains about 450 entries, some long (18 pages on symbols, units and nomenclature; 11 on elementary particles) and some short (a few less than a column). They range from instrumentation (particle accelerators, photomultipliers, transistors, thermocouples and so on), through classical physics (analytical dynamics, thermodynamics, acoustics, geomagnetism etc.), to quantum physics (liquid helium, atomic spectroscopy, nuclear structure, Josephson effect and so on). The articles are all by well-known physicists. They show great diversity in both objective and style, and there is considerable overlap between them.

How well will this new encyclopaedia meet our needs? Many of the major entries are really excellent — for example those on elementary particles, liquid crystals, vision and colour, and non-equilibrium thermodynamics, to mention just several. For greatest effectiveness, each major article should really provide a substantial reference list, but not all do. That on nuclear reactions, two pages long, provides an excellent classification of work in this subject but gives only one reference, whereas other articles, such as those on electronics, the Hubble effect, and relativity (special theory), give a wide range of graded references; perhaps this is overdone for solar energy, with one and a half pages of references for a six-page entry.

With a variety of viewpoints of the contributors, the multiple coverage could be a strength, but some consolidation would have obvious advantages. To give one illustration, the entries for baryons, hadrons, hyperons, and mesons, each about a page in length, could usefully have been combined into a four page article on hadrons, the other three entries each being reduced to one line, cross-referenced to hadrons. In addition, the coverage of different topics is not always in proportion to their relative importance. For example, the rather detailed contribution on weak neutral currents is given five pages, without any corresponding counterpart for weak charged currents. Also turbulence, one of the least understood areas of physics,

receives only one and a half pages.

Many of the articles read strangely for a newly published book, as if one is recalling a past time, some four or five years ago. For instance, quantum chromodynamics, our deepest and most promising theory of elementary particles, receives only one paragraph in each of the contributions on elementary particles, quantum electrodynamics, and unified field theory, despite the fact that it has provided an underlying basis for most of the theoretical work in elementary particle and high-energy physics over the past three years. The editors of an encyclopaedia face great difficulties, of course, but in this case they might have noted that a few of the articles called for some revision at the last moment.

The operational test of a reference book of this sort is whether information can be located rapidly. For this, the general index serves fairly well. I found that Higgs mechanism, radiocarbon dating, and

Peierls stress were in the index, as was Umklapp process, although with reference to p.732 where only articles on partial waves and partons are to be found. There is no entry for current algebra but the article on currents in particle theory is indexed nearby and led me to my goal. However there is no entry for Thomas precession, nor for photon multiplier, nor even for the Wigner-Eisenbud theory of the R-matrix and its application to resonance processes.

This encyclopaedia has a great deal to offer to scientists and engineers in general, as well as physicists. The underlying plan is sound and the articles generally authoritative. With so many first-rate contributions, it should have an assured place in all science libraries. It could be substantially improved, in my opinion, but, as things stand, it is the best compilation of its type available for physics today. □

R. H. Dalitz is Royal Society Research Professor in Theoretical Physics at Oxford University.

This is psychology?

John C. Marshall

Mindwatching. By H. and M. Eysenck. Pp.224. ISBN 0-7181-1937-1. (Michael Joseph: 1981.) £10.50. To be published in the USA by Doubleday.

THERE'S an old joke about how to select candidates for admission to psychology courses. The hapless individuals are asked the simple question "Why do you want to study psychology?" Those who reply "Because I want to *understand* people" are advised to read history or English literature; those who reply "Because I want to *help* people" are told to train as surgeons, farmers, garbage collectors or tax lawyers. Any other response secures admission to the psychology department.

Hans and Michael Eysenck would, I presume, disapprove. For them, the goal of professional psychologists is "to understand why people behave as they do, so that it will be possible to predict and change their behaviour"; this goal is to be achieved by controlled experimentation, the results of which are sometimes counterintuitive and thus undermine the sceptic's claim that my grandmother knew as much "psychology" as it is possible (or wise) for any mere mortal to comprehend. The Eysencks have accordingly produced this coffee-table volume in which the purported achievements, theoretical and practical, of experimental psychology are laid out for interested bystanders. Two questions therefore arise: First, to what extent are we presented with a fair summary of modern psychology? Second, are the social implications of current work outlined in a

responsible fashion?

The authors employ the stylistic device of describing in each chapter a so-called "key experiment", supplemented by anecdote and speculation. This is not in itself a bad strategy but it does lead the Eysencks into letting vaudeville prevail over rationality. For example, a section on "Attractiveness and jury decision-making" is introduced by the story of a famous nineteenth-century trial in which a woman accused of poisoning her lover was somewhat lucky to obtain a verdict of "not proven". The Eysencks speculate that since the defendant was "young, vivacious, and beautiful", these attributes may have influenced the jury and "helped to save her from the gallows". An experiment is then described in which mock juries who consider hypothetical cases of a relatively minor nature do indeed seem to be swayed a little by the physical attractiveness of the mock defendants. But the section then concludes with the claim that "most of the available research suggests that physical attractiveness has little or no effect on juries when serious crimes are involved". I can only make sense of this information by assuming the Eysencks believe that murdering one's lover is not a serious crime.

On other occasions the authors are unable to resist the temptation of a spectacular but fatally flawed study. They thus feature Rosenham's report in which a group of normal people were admitted to mental hospitals after falsely complaining that they heard voices and asking to be admitted. Following an average stay of 19

days the pseudo-patients were discharged with a diagnosis of "schizophrenia in remission". On the basis of this and a number of related pranks, Rosenham concluded that "It is clear that we cannot distinguish the sane from the insane in psychiatric hospitals". Very amusing, no doubt, but normal people who are not in the pay of psychologists either don't hear voices or, if they do, are not sufficiently worried by it to seek admission to hospital. The Eysencks themselves quote Seymour Kety's withering comment — "If I were to drink a quart of blood and, concealing what I had done, come to the emergency room of any hospital vomiting blood, the behaviour of the staff would be quite predictable. If they labelled and treated me as having a bleeding peptic ulcer, I doubt that I could argue convincingly that medical science does not know how to diagnose that condition" — but they are not thereby inhibited from describing Rosenham's jest as a "key experiment".

Not all of the selections are as silly as Rosenham's study. The book contains quite sensible sections on eye-witness testimony, divided attention and forgetting. Similarly, the chapter on attempts to teach sign language to chimpanzees is an improvement on many popular treatments of the topic. But these islands of sanity are lost in the surrounding sludge of trivia and titillation. What can one say of a book which proclaims that psychology should "be regarded as the most important of all the sciences" and then reports that "Small breasts were preferred by men with fundamentalist religious beliefs suffering from mild depression"?

There is little improvement when the Eysencks draw out the practical implications of their choice of topics. We are informed that a process of conditioning can turn our children into "well-integrated, honest members of society" and referred to Chapter 6 for the experimental evidence that this is so. Chapter 6, however, reports that obsessive and compulsive disorders can be treated by "behaviour therapy". In Chapter 22, a discussion of Hans Eysenck's "theory" of personality is held to support the claim that "The egalitarian principle underlying socialism is in conflict with biological reality and can only be enforced by dictatorship". Exactly how this conclusion is reached remains shrouded in mystery. An appallingly ill-controlled "experiment" on the effects of two types of play-group prefaces the remark that "the advocates of progressive teaching . . . have turned our pre-school groups, kindergartens and primary schools into permissive places of no work and all play, from which all socializing and restraining influences have been banned".

One can only hope that this grubby little opus will sink without trace. It totally fails to represent those aspects of psychology where results of some intellectual depth have been obtained in the study of perception, language and skilled action; it similarly ignores many areas of occupational, clinical and educational research where careful, thoughtful work has served to enhance the quality of life. □

John C. Marshall is in the Neuropsychology Unit, part of the Neuroscience Group at the Radcliffe Infirmary, Oxford.

Check-list of Birds of the World. For example, Terres leaves the titmouse family intact and includes the long-tailed tits (Aegithalinae) and penduline tits (Remizinae) as subfamilies rather than treating them as distinct families as has been recently practised. On the other hand, the thrushes are retained in their own family, Turdidae, and there is no mention of their current placement as a subfamily in the Old World flycatcher family, Muscicapidae.

While the book has many virtues it falls short of the stated goal of providing information on all the birds that have nested or been sighted in Alaska, Canada, Greenland, Bermuda, Baja California and the 48 contiguous states of the USA. Omissions are conspicuous, for example, in the Alaskan avifauna. While the 1978 update of the status of Alaskan birds is referenced in numerous places, and 1980 Alaskan references are also given, it is annoying that no less than 22 Alaskan species given in the 1978 publication are ignored. For instance, while the willow warbler (an Old World warbler) is discussed, nothing is said about its North American status. Only its Eurasian distribution is mentioned, so readers are not aware that it has occurred as an accidental in Alaska.

Another flaw is that the book's attractiveness is compromised by lumping colour plates together in sections. For example, located in the middle of the thrush family species accounts are 31 pages of colour plates of tanagers, thrush family, titmouse family, trogon, tropicbirds, troupial (American blackbird) family, turkey, vireo family and New World vultures and condors — rather a potpourri even though they are in alphabetical order. As with most undertakings of this magnitude other errors, mainly of editorial style, creep in. Under "Fecal Sac" we are referred to "Nests and Nestlings" but there is nothing on the sac there. A second reference under "Fecal Sac" is "Nest Sanitation" which is there, but under that title we are referred further to "Young and Their Care" which contains a discussion of nest sanitation and fecal sacs. Further minor inconsistencies are the listing of "Courtship" with sub-topics such as *courtship rituals* but not *courtship feeding*. This latter appears as a completely separate topic followed by "Courtship Flight", which then only refers the reader back again to "Courtship" and "Flight".

Despite my less-than-total enthusiasm with the *Encyclopedia*, on balance Terres has done a remarkable job in producing a scientifically accurate tome relatively free of typographical errors. With over 7 million bird-watchers in the US alone (as of 1970), of which at least 3 million were considered to be seriously interested in field ornithology, there should be a receptive audience to savour this book. □

Clayton M. White is a Professor of Zoology at Brigham Young University, Provo, Utah.

Find the (North American) bird

Clayton M. White

The Audubon Society Encyclopedia of North American Birds. By John K. Terres. Pp. 1,109. ISBN 0-3944-6651-9. (Knopf: 1980.) \$60 US only.

IN 1896 Professor Alfred Newton published his *Dictionary of Birds*. Thus a mould was cast. But it took another 68 years, until 1964, through the British Ornithologists' Union and under the editorship of A. Landsborough Thomson, for another such work to appear: *A New Dictionary of Birds*. Now, only 16 years later, another giant encyclopaedia is on the market. To me, this current volume appears to be an attempt to update a considerable body of material from the now elusive *New Dictionary*. Its scope, however, is mainly restricted to North America.

The book is designed to be a single-volume work for both layman and professional, but I suspect the lay will benefit most. There are nearly 6,000 alphabetically arranged entries and cross references, illustrated with 875 full-colour

photographs of bird species and over 800 black-and-white drawings. The scope of the entries is impressive: Birdhouse, Bird Lice, Birds as Collectors, Birds as Watchdogs, Bird Skin, Bird-Watcher, Bisexuality, Bittern, Blackburne, among the "B's" for example. Abbreviated life histories of 847 birds are provided. For each species are given a description of the Latin or Greek origin of the scientific name (a most valuable feature), the bird's geographical range, colour and distinctive morphological features, habitat, feeding habits, other names, nest, eggs, and other features of interest (such as who parasitizes whom). Terres cites over 4,000 references, ranging in date from the turn of the 1800s to 1980, all of which are listed in a bibliography. The bulk of several alphabetical sections is taken up by species accounts. The taxonomic treatment is fairly current by both European and American standards, at least in common names, but is more conservative and departs somewhat from the nomenclature of Peter's

REVIEW ARTICLE

Localization and electronic properties in amorphous semiconductors

J. Mort

Xerox Webster Research Center, Webster, New York 14580, USA

J. Knights

Xerox Palo Alto Research Center, Palo Alto, California 94304, USA

The transport and photogeneration of different classes of amorphous semiconductors are considered. These properties are affected by localization associated with long-range disorder and defects which in turn reflect the underlying chemical nature of each class.

PRESENT interest in the electronic properties of amorphous semiconductors is the result of several related factors. The demonstration^{1,2} that amorphous Si, (a-Si), like the crystalline form, can be doped to form either a *n* or *p* extrinsic semiconductor suggested new ways of using amorphous materials as electronic materials.³⁻⁶ Other classes of amorphous solids than this tetrahedral material, have been extensively studied in recent years, including chalcogenides such as amorphous selenium (a-Se), amorphous arsenic triselenide, (a-As₂Se₃) and amorphous molecular or organic solids⁷⁻¹⁰. It is now clear that although amorphous solids have certain characteristic features in common, there are also distinctive differences. Our purpose here is to compare and contrast the electronic properties of these three groups of amorphous solids—the chalcogenides, the tetrahedrally bonded materials and molecular systems.

The most obvious consequence of disorder in amorphous solids is that intrinsic localized states exist within the energy gap. The experimental and theoretical problems of understanding the effect of disorder on the photoelectronic properties of solids are considerable, but much progress has been made in the past decade in three directions. Light has been thrown on the origin and nature of localized states, and their relationship with the specific chemical nature and the bonding of the constituent building-blocks. The mechanism of charge transport and photogeneration has been partially understood; quantitative studies of the consequences of doping have begun. In what follows, these three areas will be discussed for the three general classes of amorphous solids.

Nature of localized states

In the development of crystalline semiconductors, major conceptual advances such as the understanding of band-gaps arose from the recognition of the long-range periodicity and symmetrical arrangement of the atomic building blocks—intrinsic features which are essentially independent of the method of preparation. Most technical applications of crystalline semiconductors and their associated physics are, however, connected with deviations from idealized order. The localized states within the band-gap produced by defects, impurities, surfaces and interfaces control many properties, particularly those involving carrier transport and generation-recombination processes; such perturbations are strongly influenced by both the method of preparation and subsequent treatment.

Viewed in this way amorphous semiconductors exhibit remarkably similar features. The existence of band gaps in the absence of long-range periodicity has a firm theoretical basis in tight-binding approaches. It has been predicted^{11,12}, based on Anderson's work on localization¹³, that even in the absence of defects the potentials fluctuating because of the disorder would result in localized tail states at the conduction and valence band edges. Figure 1 shows that the density of states distribution in an amorphous solid can be divided into three regions. For energies greater than ϵ_c and less than ϵ_v , electronic states are extended or band-like in character. For energies close to these values, the scattering length of the electron wave function approaches interatomic distances. Conduction then occurs as a Brownian diffusive motion with estimated mobilities between 1 and

Fig. 1 Density-of-state distributions for a-Si specimens. *a*, Glow discharge specimen, $T_d \approx 520$ K; *b*, glow discharge specimen, $T_d \approx 350$ K; *c*, evaporated specimen. The solid lines indicate results obtained from field-effect experiments and the arrow on each curve shows the position of the Fermi level. E, extended states; T, tail states; G, gap states. (After ref. 15.)

Fig. 2 Concentration dependence of the drift velocity of holes in a mixed doped polymer showing the trap-controlled hopping process. NIPC concentrations: $\circ$, $1 \times 10^{21} \text{ cm}^{-3}$; $\bullet$, 0; $*$, $2 \times 10^{20} \text{ cm}^{-3}$. The points correspond to samples with varying concentrations of TPA, which has a lower ionization potential than NIPC. (After ref. 25.)

$10 \text{ cm}^2 \text{ V s}^{-1}$ (ref. 14). Just below ϵ_c and above ϵ_v there exist the tail states due to Anderson localization that are associated with satisfied but distorted bonds. Anderson localization begins when U_0/J (where U_0 is the range of site energy disorder and J is the transfer integral between nearest neighbours) exceeds a critical value at which an electron at a given site at temperature $T = 0$ becomes localized, that is, it can no longer diffuse away. Defects arising from incomplete or dangling bonds or impurities give rise to the deep lying gap states. As in the crystalline case, the nature and density of these states depend on conditions of preparation and treatment.

The determination of detailed density of state distributions has proved difficult. In the case of amorphous Si some information has come from studies of the field-effect¹⁵ as shown in Fig. 1. Although quantitative details and the relative contributions of surface and bulk states are uncertain, the general features are consistent with independent studies of conductivity, thermopower and drift mobility. The distribution and number of localized states in a-Si:H prepared by glow discharge of silane may be controlled by the preparation conditions (Fig. 1). This is partly because hydrogen satisfies dangling silicon bonds at defects in the extended amorphous network. Many of the associated electronic defect states are thereby removed from the forbidden gap, which suggested that impurity doping above the residual levels might be possible^{1,2}.

These features are general and may be applied to the covalently bonded chalcogenides. However, all efforts to observe a significant field-effect have failed¹⁶. This is surprising¹⁷ because the efficiency of amorphous Se in electrophotography indicates a substantial carrier range of $\sim 50 \mu\text{m}$, which implies gap state densities $\sim 10^{14} \text{ cm}^{-3}$. Recent intrinsic defect models for gap states, which take account of the specific atomic bonding of chalcogen atoms coupled with the law of mass action, may resolve this conflict^{18,19}. The valence alternation pair defects (VAPS) lead to a thermodynamic equilibrium of D^+ and D^- states, which effectively make the Fermi level independent of

the actual density of the state; in other words the Fermi level cannot be moved relative to the bands either by an applied field as in the field effect experiment or doping.

In disordered molecular solids, the building blocks are molecules. Even in molecular crystals the weak Van der Waal's forces between molecules lead at best to very narrow energy bands. In this case, the disorder, associated with pendant group polymers such as poly(*N*-vinylcarbazole) or molecularly-doped polymers means that extended states cannot be involved⁸. Such systems, particularly molecularly-doped polymers, therefore must consist of purely localized states which are associated with the dopant molecules⁸, in this way they are almost ideal for studying phenomena associated with localized states.

Electronic transport

The most unambiguous information on electronic transport in amorphous materials has come from measurements of the drift mobility by the time-of-flight technique. In this method the time, t_T , for a sharply defined spatially and temporally photoexcited charge sheet to cross a sample of known thickness L , with an applied bias field E , is measured. Because $t_T = L/\mu E$, the carrier mobility μ can be directly determined. Table 1 gives typical values of the drift mobilities for both electrons and holes in representative amorphous materials. In all cases the mobilities are unity or less and are thermally activated. There are various explanations for the nature of this electronic transport. No conduction can occur in the localized tail and gap states at $T = 0$. At finite temperatures, however, thermally activated hopping transport between localized states can occur and the mobility $\mu(\epsilon)$ at an energy ϵ can be written²

$$\mu(\epsilon) = \frac{1}{6} \frac{eR^2(\epsilon)}{kT} \nu_{ph} \exp(-2\alpha R) \exp(-W/kT) \quad (1)$$

where R is the average distance between sites at energy ϵ and is determined by the density-of-state distribution. The term $\exp(-2\alpha R)$ describes the overlap of the wave functions on neighbouring hopping sites and α^{-1} is a measure of the spatial decay of the wave function^{2,7}; $\nu_{ph} \exp(-W/kT)$ represents the probability that the localized carrier hops to a site with energy higher by W . This transport mechanism solely controlled by hopping from one localized state to another should be observed in amorphous materials. However, before doping studies proved possible, this mechanism could only be deduced with some ambiguity from the combined observation of low mobility values and thermal activation as these features are also characteristic of transport involving extended state transport modulated by trapping in energetically shallow traps²⁰.

Direct observation of pure hopping between localized states became possible with the advent of molecularly-doped polymers²¹. These are otherwise electrically-inert polymers into which molecules can be dispersed at high controllable concentrations $< 10^{21} \text{ cm}^{-3}$ and constitute a random ensemble of molecules which have essentially no mutual interaction. As a result they consist of pure localized states without the complication (and advantage) of extended states. Measurements of the effective mobility by the time-of-flight technique as a function of

Table 1 Representative hole (electron) drift mobilities at room temperature for examples of different types of amorphous materials

	$(\text{cm}^2 \text{ V}^{-1} \text{ s}^{-1})$	$(\text{cm}^2 \text{ V}^{-1} \text{ s}^{-1})$
a:Se	$(5-8) \times 10^{-3}$	$0.11-0.19$
a:As ₂ Se ₃	—	$\sim 10^{-5}$
a-Si:H	0.1	5×10^{-4}
PVK	—	$< 10^{-6}$

See refs 2, 8, 27.

Table 2 Amorphous materials are different and may be categorized according to how the conductivity ($\sigma = ne\mu$) is affected by doping

Chalcogenides	Tetrahedral	Molecularly doped polymers
σ , relatively weak dependence	σ strong dependence	σ strong dependence
$\Delta\sigma$ related to $\Delta\mu$	$\Delta\sigma$ related to Δn	$\Delta\sigma$ related to Δn and $\Delta\mu$
(Fermi level immobile)	(Fermi level moves)	

An example of such dispersive transits in a-As₂Se₃ are shown in Fig. 3. In Fig. 3a a transit signal, showing the photoinduced transient current versus time in linear scales, is essentially featureless. The same transit signal in Fig. 3b is displayed with logarithmic current and time scales. The predicted change in slope when the leading carriers have transited the sample is indicated at t_T which shifts to shorter times at higher fields, E . The concept of mobility now loses its meaning as no average velocity of the charge packet is definable, and the predicted thickness-dependent mobilities have been observed. This type of dispersive phenomena appears in recombination processes, time dependent luminescent decay and trapping²⁹.

Fig. 5 a, Room-temperature conductivity σ_{RT} of n and p-type amorphous Si specimens as a function of the gaseous impurity ratio. For the right-hand curve, this is the number of phosphine to silane molecules in the gas mixture used for specimen preparation. On the left it is the corresponding diborane to silane ratio. The centre refers to undoped specimens. (After ref. 1.) b, log-log plot of transit time and resistivity ρ versus concentration N of: $\circ$, $\bullet$, Ni; $\ast$, Mn; $\square$, $\blacksquare$, Cu doped a-As₂Se₃. (After ref. 37.)

Fig. 6 a, Chemical control of conductivity in a molecularly-doped inert polymer matrix. Fractional oxidation of neutral transport molecules T is achieved by controlled addition of an oxidizing agent SbCl₅. The oxidized transport molecules are radical cations T⁺ which constitute free carriers. Progressive oxidation of the neutral molecules leads to increasing free carrier concentrations at the expense of the neutral molecules necessary for the transport mechanism. b, Dependence of conductivity on concentration of oxidized transport molecules N_s . The molecule tri-p-tylamine (TTA) is dispersed in Lexan[®] polycarbonate. The total molecule concentrations were: $\square$, $8.6 \times 10^{20} \text{ cm}^{-3}$; $\triangle$, $7.2 \times 10^{20} \text{ cm}^{-3}$; $\circ$, $0.86 \times 10^{20} \text{ cm}^{-3}$. (After ref. 40.)

Photogeneration

Photogeneration is a critical process in any photoelectronic material. The way in which absorbed photons produce photogenerated carriers is affected by disorder within the material. Geminate recombination is likely to be a limiting step in the photogeneration process in materials where the mean free paths of photoexcited carriers are characteristically low³⁰—a natural condition of amorphous materials. Figure 4a illustrates this photogeneration process whereby the initial photoexcitation leads to electron-hole pairs, which diffuse within their mutual Coulomb well. There is a finite probability, which decreases with applied field, that the pair will combine at the initial excitation site rather than dissociate into a free electron and a hole. Three critical parameters are; Φ_0 , the efficiency of production of thermalized electron-hole pairs per absorbed photon; r_0 , a characteristic thermalization length (related to the mean free path); and r_c , the coulomb radius or the distance at which the coulomb energy $\sim kT$. Precise measurements³⁰ for a-Se indicate Φ_0 (the maximum possible quantum efficiency) is unity and there is evidence that this also applies to a-Si (refs 31, 42) and a-As₂Se₃ (ref. 32). For disordered organic systems, however, Φ_0 can be ~ 0.1 or even smaller. This reflects the existence of intramolecular relaxation processes, radiative or non-radiative, which compete with the photogeneration or dissociation of the photoexcited molecule³³. Figure 4b shows a treatment of this problem due to Onsager³⁴ for a material with $\Phi_0 = 1$ and the dielectric constant of a-Se ($\epsilon = 6.0$). The various curves are for

different assumed values of r_0 . For a given value of r_0 the quantum efficiency remains field independent up to $\sim 10^4 \text{ V cm}^{-1}$ after which it becomes field dependent and approaches unity in a sufficiently high field. As r_0 increases the initial or zero field quantum efficiency increases and the subsequent field dependence decreases. Where a curve for a particular value of r_0 lies on the absolute quantum efficiency axis depends on the coulomb radius of the material which is determined by the dielectric constant. Typical coulomb radii are $\sim 49 \text{ \AA}$ for a-Si, $\sim 100 \text{ \AA}$ for a-Se and $\sim 250 \text{ \AA}$ for most organics, this would indicate descending order for the photogeneration efficiency for comparable values of r_0 and Φ_0 .

Experimental data for a-Se shown in Fig. 4b explain the macroscopic observation that a-Se is more panchromatic in absorption than in photosensitivity³⁰. This arises because r_0 being wavelength dependent ranges from $70 \text{ \AA}$ at a wavelength $4,000 \text{ \AA}$ to $10 \text{ \AA}$ at a wavelength of $6,000 \text{ \AA}$. Recent evidence shows that photogeneration in a-Si:H and a-As₂Se₃ may also be geminate^{31,32}. Unlike the case of a-Se, however, r_0 has at most a very weak wavelength dependence. A field-dependent quantum efficiency has implications for ultimate solar cell conversion efficiencies, this is because of the spatial field distribution within the barrier of Schottky or p-n cells which, with the absorption profile of the light, leads to photons being absorbed in a range of fields and effectively leads to a spatial distribution of quantum efficiencies³⁵.

Doping of a-semiconductors

One of the most important advances in the field of amorphous materials has been the demonstration that n or p type a-Si:H and a-Ge:H could be produced by appropriate doping; there is no evidence that this applies to chalcogenides, although it is possible in a-C:H (ref. 36). It seems possible to group amorphous materials according to the way in which doping affects their electrical conductivity σ , as indicated in Table 2. Detailed studies of doping in amorphous Si and, to a lesser degree, in a-carbon indicate that σ is strongly dependent on doping. Conductivity, thermopower and drift mobility measurements demonstrate that this is associated with a shift in the Fermi level which affects both the type and density of carriers controlling the conductivity (see Fig. 5a)². On the other hand, relatively small changes in the transport occur, except for special cases such as inter-donor hopping in compensated samples. By contrast, extensive doping studies of chalcogenides, for doping levels well below the alloy range, do not result in significant movement of the Fermi level or change in conductivity³⁷. However, substantial and systematic changes in the drift mobility of holes have been reported in a-As₂Se₃. Because the drift mobility can be the microscopic mobility modified by trapping, the fact that these changes in the drift mobility are not reflected in the conductivity (see Fig. 5b) indicates that the impurities are changing the density of traps which controls the mobility³⁷. This

insensitivity of the position of the Fermi level in chalcogenides to doping is consistent with the absence of a field effect and with other defect models^{18,19} based on valence alternation pair defects, D^+ and D^- , which are positively and negatively charged defects whose creation is governed by the law of mass action. Such defects produced under thermal equilibrium effectively pin the Fermi level. It is possible that doping of chalcogenides in non-equilibrium conditions could result in an unpinning of the Fermi level and production of extrinsic semiconductors. Whether this can be done in a stable manner is unclear.

Recent studies confirm that the densities of defects can be affected by heating³⁸. Thus photoelectronic properties of chalcogenides immediately after preparation are dependent on thermal history. Characteristic equilibrium behaviour, independent of the method of preparation is, however, achieved after annealing^{38,39}. The latter are consistent with Spear's observation that the most remarkable feature of chalcogenides is the reproducibility of their mobility values, a feature probably unmatched by even the best crystalline semiconductors¹⁶. This then, seems to be related to the ability of chalcogenide glasses to self-anneal defects efficiently.

In the disordered organic materials, doping is accomplished by the controlled chemical oxidation of some of the dopant molecules⁴⁰. These radical cations are the equivalent of 'free' carriers because electrons can hop from neighbouring neutral molecules and thereby the 'free' hole propagates (see Fig. 6a). Thus at low oxidation levels the conductivity rises as the 'free'-carrier concentration rises. However, because no extended states exist and free carriers are highly localized and associated with specific molecules, such free carriers are created at the expense of transport paths. In the extreme case, where the total oxidation has occurred, none of the neutral molecules necessary for the transport process remain and the conductivity must go through a maximum as indicated in Fig. 6b (ref. 40). It is possible to produce films containing $\sim 10^{20}$ cations cm^{-3} which form what Mott has termed a degenerate polaron gas⁴¹. In this case, therefore, the conductivity is controlled by changes in both free carrier concentrations and mobility where these are not independent.

Conclusions

We have outlined the transport and photogeneration properties in three general groups of amorphous materials which make up most of materials known as amorphous semiconductors. In particular the different effects of localization of electronic wavefunctions due to long range disorder and those due to defects have been considered. The picture that emerges is that although features characteristic of the disordered state do exist, amorphous materials exhibit a rich diversity of behaviour which reflects their underlying chemical composition. In this sense the similarities between disordered and crystalline solids are closer than was originally perceived.

Resonant structure of the asteroid belt

Stanley F. Dermott & Carl D. Murray

Center for Radiophysics and Space Research, Space Sciences Building, Cornell University, Ithaca, New York 14853, USA

Statistical techniques are applied to asteroid orbital data in an attempt to define the characteristics of the Kirkwood gaps in the distribution of the asteroids. A significant tendency is found for the eccentricities and inclinations of asteroid orbits to increase away from the gaps. These effects are observed throughout the distribution of main-belt asteroids. They are not merely confined to the immediate vicinities of the resonances and are not caused by observational selection effects. There is no evidence that the magnitude-frequency distribution of the asteroids changes near the gaps. Evidence is given for the existence of gaps in Hirayama families, possibly of a different nature from the classical Kirkwood gaps at locations corresponding to high order commensurabilities with Jupiter. These results support the theory that the Kirkwood gaps were formed by gravitational processes acting on individual asteroids throughout their lifetimes.

ALTHOUGH gaps in the distribution of the asteroid population are generally accepted to be associated with resonances with Jupiter¹, the exact mechanism which produces the gaps remains in dispute. The four major hypotheses² proposed to explain these Kirkwood gaps¹ are: (1) the statistical hypothesis (the proposal that asteroids are librating about the gaps and are therefore only rarely seen crossing the exact resonances), (2) the gravitational hypothesis (the gaps are formed by purely gravitational interactions with Jupiter), (3) the collisional hypothesis (the gravitational effects of Jupiter increase collision rates within the gaps, causing a wearing down or removal of material) and (4) the cosmogonic hypothesis (the gaps represent regions where asteroids failed to form during the early history of the Solar System). Although there are problems associated with each hypothesis, recent work³⁻⁶ has provided convincing evidence against the statistical hypothesis. It is important, therefore, to recognize which properties of the Kirkwood gaps could help to distinguish between the gravitational, collisional and cosmogonic hypotheses. Little work has been carried out in this field partly because of the failure to apply established statistical methods to the wealth of data available.

Resonance

The integral with respect to time of the expansion of the disturbing function for the gravitational interaction between two bodies (see, for example, ref. 7) contains divisors which become small when the ratio of the mean motions is close to a simple fraction of the form $p/(p+q)$, where p and q are integers. Such locations in the asteroid belt correspond to resonances with Jupiter and q is called the order of the resonance. The strength of a given resonance depends on several factors which include the distance between the bodies and the value of q : a large value of q implies a weak resonance. In the present study, we include all resonances with $q \leq 6$ which lie between the 1/3 and 1/2 resonances with Jupiter. These are the 1/3, 3/8, 2/5, 3/7, 4/9, 5/11 and 1/2 resonances. The limit $q \leq 6$ is arbitrary but reasonable. If Kirkwood gaps do have any characteristics other than a lack of asteroids, one would expect them to be more prominent in the vicinity of the strongest resonances.

Asteroids outside the 1/2 resonance are omitted. The number of asteroids between this resonance and Jupiter is small and some resonances in this region are associated with groupings of asteroids rather than gaps (see ref. 6). Asteroids inside the 1/3 resonance are also omitted because their orbits may have been influenced by Mars as well as by Jupiter⁸. Furthermore, the

resonances in this region, which is distant from Jupiter, are weak.

The *Tucson Revised Index of Asteroid Data* (TRIAD) is a convenient source of information on the orbital elements and physical properties of asteroids. In particular, Williams⁹ has calculated sets of proper elements (orbital elements after the effects of short-period oscillations have been removed) for 1,687 asteroids. Hirayama¹⁰ recognized certain groupings in the distribution of proper elements which he called families. The inclusion in our study of large numbers of asteroids whose orbital elements are similar or correlated for reasons other than those associated with resonance would give misleading results. We therefore exclude any asteroid which is designated a family member in the TRIAD file.

Thus, our study is confined to main-belt, non-family asteroids with semi-major axes a' in the range 2.50–3.28 AU whose proper elements are listed in the TRIAD file. 757 asteroids satisfy these requirements.

Statistical method

For each asteroid in our chosen population we calculate R , the ratio of the mean motions of Jupiter and the asteroid ($R < 1$). For each value of R we find the fractions R_2 and R_1 in the set 1/3, 3/8, 2/5, 3/7, 4/9, 5/11, 1/2, which bound R most closely from above and below. Then, using a method similar to that of Dermott¹¹, we define a parameter δ by

$$\begin{aligned} A &= (R - R_1)/(R_2 - R_1) \\ \delta &= 2(A - B) \\ B &= 0 \text{ if } A \leq 1/2 \\ B &= 1 \text{ if } A > 1/2 \end{aligned} \quad (1)$$

Thus, $-1 \leq \delta \leq +1$ and is a measure of the displacement of the asteroid from the nearest strong resonance. $\delta = 0$ corresponds to exact resonance and $|\delta| = 1$ is the greatest displacement from resonance that an asteroid can have.

Clearly the number density of asteroids systematically increases and decreases to a variable degree between the strong resonances. By defining δ we can superpose distributions to obtain a single distribution which is characteristic of the population as a whole. The relationship between δ and any other property of the asteroids or their orbits, such as their absolute magnitudes, types, diameters or proper eccentricities, can then be analysed.

Fig. 1 *a*, A direct plot of absolute magnitude against δ (a measure of the displacement from the nearest strong resonance) for the 757 asteroids in the TRIAD file which have semi-major axes in the range 2.50–3.28 AU and which are not members of recognized families. The apparent lack of asteroids with large absolute magnitudes is an observational selection effect. *b*, A smoothed number density contour plot obtained by applying running box methods to the data shown in *a*. Note how the number density increases continuously as $|\delta|$ increases: there is no plateau. This implies that the effects of resonance pervade the whole distribution of main-belt asteroids. For absolute magnitude ≤ 10.3 the number density decreases as the absolute magnitude decreases—that is, there are relatively few asteroids of low magnitude. It is a combination of these two trends which results in the general V-shape of the contour plot.

Kirkwood gaps

Figure 1*a* plots absolute magnitude, $B(1, 0)$, against δ for all the asteroids in our chosen population. The absence of objects near $\delta = 0$, which corresponds to exact resonance, is the only accepted characteristic of Kirkwood gaps. It is useful to study a contour plot of the data shown in Fig. 1*a* and this is shown in Fig. 1*b*, which was obtained by applying a running box method to our data set. Note that as $\delta \rightarrow \pm 1$ the number density monotonically increases: the effects of resonance pervade the whole distribution of main-belt asteroids.

It has been suggested (see, for example, ref. 12) that larger objects avoid the gaps more than the smaller objects, and on first

examination Fig. 1*b* seems to confirm this. However, a combination of a decrease in number density with decreasing magnitude and an increase in number density with increasing $|\delta|$ would always give the illusion that low-magnitude objects avoid the gaps, even if the asteroids were in fact randomly distributed on either side of the resonances. Alternative methods are needed to settle this question.

By ordering our chosen population in absolute magnitude and calculating running means, we can plot the mean value of $|\delta|$ against the mean absolute magnitude (Fig. 2*a*). In Fig. 2*a*, and also Figs 2*b* and 3, the running box always contains 100(=N) asteroids and was shifted through the chosen population with a step length of 10 asteroids.

The central limit theorem (see, for example, ref. 13) relates σ , the standard deviation of the distribution of the means of the samples, to σ_p , the standard deviation of the chosen population by

$$\sigma = \frac{\sigma_p}{\sqrt{N}} \quad (2)$$

where N is the number of objects in each sample.

Figure 2a shows that $\langle |\delta| \rangle$ increases as absolute magnitude decreases. The result is significant at $\geq 3\sigma$ level. Thus, larger objects in our chosen population do avoid the gaps more than the smaller objects. However, by ordering our chosen population by sine of proper inclination, we can also show that proper inclination increases as $\langle |\delta| \rangle$ increases (Fig. 2b). Again, the result is significant at $\geq 3\sigma$ level. Furthermore, the data shown in Fig. 2 seem to be negatively correlated, and this is confirmed in Fig. 3, which plots the mean absolute magnitude against mean sine proper inclination.

That mean absolute magnitude should decrease as mean proper inclination increases is a consequence of observational selection¹⁴. Faint asteroids have a greater probability of discovery if their inclinations are low and close to the ecliptic. Thus, although the trends shown in Fig. 2 are undoubtedly real, it is probable that only one of them is a fundamental property of

Fig. 2 A plot of the mean value of $|\delta|$ against: *a*, the mean absolute magnitude; and *b*, the mean sine proper inclination obtained by applying a running box method to the chosen population of 757 non-family asteroids which were sorted in order of increasing *a*, absolute magnitude; and *b* sine proper inclination. The σ levels are derived by the application of the central limit theorem to the distribution of the means of the samples of the population. The running box (and hence each sample) contained 100 asteroids and was stepped through the population 10 asteroids at a time. *a* Shows that low-magnitude objects do tend to have larger values of $|\delta|$, that is, that low-magnitude objects do avoid the gaps to a greater degree than do the high-magnitude objects. *b* Shows that there is a tendency for displacement from resonance to increase with inclination. In both *a* and *b* the result is significant at $\geq 3\sigma$ level.

Fig. 3 A plot of the mean value of absolute magnitude against mean sine proper inclination obtained by applying a running box method to our chosen population of 757 non-family asteroids which were sorted in order of increasing sine proper inclination. The correlation is consistent with the effects of observational selection which produce an excess of high magnitude, low inclination objects¹⁴.

Kirkwood gaps and the result of resonance rather than observing procedures. We must now determine which trend is the fundamental one, and we do this by analysing a data set which is free of all observational selection effects.

Bias-free statistics

On the basis of results from the McDonald survey¹⁵, Kiang¹⁴ estimated that the catalogued asteroid population is 95% complete up to mean opposition magnitude, $B(a, 0) = 15$. Mean opposition magnitude is related to absolute magnitude by

$$B(a, 0) = B(1, 0) + 5 \log a(a - 1) \quad (3)$$

where a is the semi-major axis of the asteroid in AU. Furthermore, Kiang points out that of the 587 new objects detected in the survey only two had apparent magnitudes < 14 . To ensure complete elimination of all observational selection effects, even at the risk of being over-conservative, we adopt as an upper limit that value of absolute magnitude which corresponds to mean opposition magnitude 14 at the largest semi-major axis of our chosen population, 3.25 AU. This gives us (see equation (3)) the conditions

$$\begin{aligned} B(1, 0) &< 9.68 \\ B(a, 0) &< 14.00. \end{aligned} \quad (4)$$

Of our chosen population of 757 asteroids, 144 satisfy the above conditions. These asteroids constitute our bias-free set.

Using the bias-free set we have repeated the plot of $\langle |\delta| \rangle$ against $\langle B(1, 0) \rangle$ and have found no significant trend. The set yields no evidence that the magnitude-frequency distribution of the asteroids changes near the Kirkwood gaps. However, by repeating the plot of $\langle |\delta| \rangle$ against $\langle \sin i' \rangle$ we have found that the trend shown in Fig. 2b persists. Thus, we conclude that it is the latter which is of fundamental importance and that the trend shown in Fig. 2a is merely a consequence of observational selection effects.

We have also discovered that, in addition to the proper inclinations i' , the proper eccentricities e' also tend to increase away from the gaps. Here, these trends are best illustrated by Fig. 4 in which we plot $\langle V \rangle$ against $\langle |\delta| \rangle$, where

$$V = (e'^2 + \sin^2 i')^{1/2} \quad (5)$$

We consider it significant that the trend shown in Fig. 4 does not level off for large values of $|\delta|$, suggesting that the effects of resonance are not confined to the immediate vicinities of the resonances, but pervade the whole distribution of main-belt asteroids.

Themis family

Franklin *et al.*¹⁶ have recently suggested that the Kirkwood gaps were formed early in the history of the Solar System at a time when the asteroids moved in near-circular, near-coplanar orbits and low-velocity collisions were frequent. They consider that the present high values of inclinations and eccentricities of orbits in the asteroid belt were produced later by some process unrelated to gap formation. We can now see that their hypothesis does not account for the characteristic trends in i' and e' which we have discovered. Further evidence contrary to their hypothesis may be provided by the Hirayama families.

The 144 asteroids that constitute our bias-free set are among the largest asteroids in the main belt. Because the lifetime of an asteroid against collisions is proportional to $\sqrt{D}$, where D is the asteroid diameter¹⁷, this set also consists of some of the oldest asteroids. It would be of interest, therefore, to look for gaps in the distributions of objects which are probably relatively recent additions to the asteroid population. The larger asteroid families are generally believed^{18,19} to be the results of collisional disruption of single bodies. The Eos family is estimated²⁰ to have been formed $\geq 10^6$ yr ago, while the Themis family is thought to be somewhat older because of the larger spread of its orbital elements. A large spread in semi-major axes increases the likelihood of sufficiently strong resonances occurring within a given family. The Themis family, with 62 catalogued members⁶ lying between 3.08 and 3.18 AU, provides the best set of relatively young asteroids in which to search for gaps associated with resonances.

There are five resonances with $q \leq 11$ located within this family. When we apply a running box method to the distribution of a , we find gaps associated with the two strongest resonances (Fig. 5). In addition, the family seems to be bounded on one side by the 5/11 resonance (3.075 AU). One may question whether these gaps are real, in the sense that they represent a genuine absence of material or whether, because family members are identified by clustering of orbital elements, they represent the failure to identify asteroids in these regions as family members because their eccentricities and inclinations, but not, perhaps, their semi-major axes, have been altered by the effects of resonance. The answer to this important question may be obtained from more complete studies of background asteroids in

Fig. 5 The distribution of the 62 asteroids in the Themis family as a function of proper semi-major axis. The plot was obtained using a running box method with a box length of 0.01 AU and a shift of 0.001 AU between data points. $N(a')$ is the number of asteroids per unit AU contained in each box. The smooth curve represents the best gaussian fit to the data. A gaussian distribution is characteristic of catastrophic disruption²¹. The location and approximate relative strength of all resonances up to and including order 11 which lie in the region of the Themis family are shown. The family appears bounded to the left by the 5/11 resonance. The strong 1/2 resonance lies at 3.28 AU. The two strongest resonances which lie in the Themis region (6/13 and 7/15) coincide with gaps in the distribution. These gaps may be of a similar nature to the Kirkwood gaps or they could be regions where the resonances have altered the proper elements of asteroids causing them to be overlooked as potential Themis family members. Observations of the physical properties of background asteroids in these regions should help to distinguish between these hypotheses.

these gaps to determine whether or not they have the physical characteristics of Themis members.

On the basis of our studies of the Themis and other families, in particular, the Eos and Koronis families, we tentatively conclude that the gaps in their distributions of semi-major axes are real and thus that some Kirkwood gaps have been formed since the time of formation of the Solar System.

Conclusions

When the bias in the data due to observational selection is removed, there is no significant tendency for low-magnitude objects to be further away from the resonances than the high-magnitude objects. Such a magnitude effect, if found, would have supported the collisional hypothesis for the origin of the gaps.

There is a significant tendency for objects further away from the resonances to have larger eccentricities and inclinations. The process responsible for the formation of the Kirkwood gaps seems preferentially to have removed those objects near the resonances which had large values of e' and i' . Since the magnitude of the gravitational disturbing function acting on an asteroid increases with the eccentricity and the inclination of the asteroid, our results strongly suggest that it is the gravitational effect of Jupiter, acting on individual asteroids, which is responsible for the formation of the Kirkwood gaps. It is possible that such a mechanism has produced the gaps over the lifetime of the Solar System, but further studies of Hirayama families should provide more accurate measurements of the timescale of such a process.

The Kirkwood gaps are not simply regions of small asteroid number density, neither are they restricted to the immediate vicinities of the resonances, for the effects of resonance seem to pervade the entire belt of asteroids between the 1/3 resonance and Jupiter itself. The characteristics we have described should place severe constraints on any theory of the formation of the Kirkwood gaps. They also challenge our understanding of the dynamical stability of the Solar System.

We thank P. Goldreich, J. Gradie and T. C. Van Flandern for helpful discussions and B. Zellner for providing us with a copy of the TRIAD file. This research was supported by NSF grant AST 79164-74-A01.

Fig. 4 A plot of the mean value of $V = (e'^2 + \sin^2 i')^{1/2}$ against the mean value of $|\delta|$ obtained by applying a running box method to the bias-free set of 144 non-family asteroids which were sorted in order of increasing $|\delta|$. For this plot, the running box contains 50 asteroids and there is a shift of two asteroids between data points. Note that the plot has no plateau: the trend is present throughout the distribution. This tendency for both e' and i' to increase with increasing $|\delta|$ is a fundamental property of the Kirkwood gaps and is indicative of the effects of gravitational forces acting on individual asteroids as a possible mechanism for the origin of the Kirkwood gaps.

Interacting genes in nematode dauer larva formation

Donald L. Riddle, Margaret M. Swanson & Patrice S. Albert

Division of Biological Sciences, University of Missouri, Columbia, Missouri 65211, USA

The dauer larva of Caenorhabditis elegans is a developmentally arrested stage induced by starvation or overcrowding. Mutant genes controlling the ability to form dauer larvae interact in a way which allows them to be ordered in a pathway. Mutant phenotypes suggest that the pathway corresponds to neural processing of environmental stimuli.

To the extent that the development of organisms is controlled by genes which act in sequence¹, it should be possible to determine a hierarchy of genes affecting the expression of certain traits. What follows is an account of a study, in the language of classical genetics, of the hierarchical relationship between the genes involved in the formation of the so-called dauer larval stage of the free-living soil nematode *Caenorhabditis elegans*. The genetic and anatomical simplicity of the organism^{2–5} fit it for such a study. Our work shows, however, that the expected hierarchy is surprisingly intricate.

Larvae of *C. elegans* undergo four moults (Fig. 1), at which the cuticle is replaced, but at the second may enter the 'dauer' or 'persistent' (German: *dauer* = hard, enduring) state⁶ in response to starvation or overcrowding. Thus arrested in development but specialized for survival and dispersal⁷, dauer larvae survive exposure to detergents and other chemicals⁸, do not feed because their mouths are plugged (Fig. 2) and may survive for months until they encounter food, moult and resume development. The duration of the dauer stage seems not to affect post-dauer longevity, suggesting that ageing is interrupted⁹.

Table 1 Suppression of dauer-constitutive mutations by dauer-defectives

CB1375 (<i>daf-18 IV</i>)	+	+	–	–	–	–	–

+ Indicates that, in a particular constitutive-defective double mutant, the constitutive phenotype is suppressed (the defective mutation is epistatic). – Indicates gene pairs in which the constitutive is epistatic (no suppression of the constitutive phenotype). In cases where suppression is not complete (*daf-6* and *daf-16*), the fraction of the double-mutant population which escapes dauer formation is given in parentheses as per cent suppression. As the only available mutant alleles of these genes are slightly leaky dauer-defectives, a low residual level of gene activity may account for reduced efficiency of suppression. Dauer-defective strains are all single mutants with allele numbers corresponding to the strain numbers given. Gene names and linkage groups are given in parentheses. The multiply-marked dauer-constitutive strains have the following genotypes, where allele numbers are given in parentheses after the corresponding gene name: DR194, *dpy-11(e224)daf-11(m47)unc-39(e257)V*; DR189, *dpy-5(e61)daf-8(e1393)unc-29(e1072)II*; DR133, *dpy-1(e1)daf-7(e1372)unc-32(e189)III*; DR202, *unc-24(e138)daf-14(m77)IV*; DR204, *daf-1(m40)dpy-4(e1166)IV*; CB2196, *daf-4(e1364)unc-32(e189)III*; DR130, *dpy-1(e1)daf-2(e1370)unc-32(e189)III*. Because it was impossible to predict in advance if a double mutant would be constitutive or defective (or even viable), closely linked visible markers were used to identify the presence or absence of *daf* alleles in newly constructed strains. To construct the strains, males homozygous for a dauer-defective (suppressor) mutation were crossed with *is* dauer-constitutive hermaphrodites carrying closely linked, flanking mutations. Heterozygous F₁ hermaphrodites produced in these crosses were wild type in phenotype, and segregated dumpy, uncoordinated animals by 'selfing' at 15 °C. The dauer-constitutive phenotype is not expressed at 15 °C. In each test, 15 marked segregants were incubated at 25 °C to determine if suppression occurred. If the suppressor gene is unlinked, three-quarters of the marked animals are expected to carry the suppressor gene in either the heterozygous or homozygous state. All such animals segregate homozygous progeny which, in the case of suppression, will grow to maturity at 25 °C. If there is no suppression, all progeny become dauer larvae. In cases where closely linked genes were tested, recombinants carrying both mutations were selected by using an intervening visible marker as in the case of *daf-8* and *daf-16*. Starting with a heterozygote (+ + *daf-16/daf-8 unc-29* +), a *daf-8 daf-16* recombinant was selected by picking F₁ progeny which are dauer-constitutive, but not uncoordinated (*daf-8 + daf-16/daf-8 unc-29* +). At 15 °C, this heterozygote segregated the double homozygote required to test the epistatic relationship of *daf-8* and *daf-16* at 25 °C. Crosses with the *daf-10* mutant are not included here. Appropriate double mutants were constructed by another method¹², because homozygous *daf-10* males do not mate¹¹. All the constitutive mutations except *daf-4* have been combined with *daf-10*, and each failed to be suppressed.

Fig. 1 The life cycle of *C. elegans*. The duration of each developmental stage during growth at 25°C on Petri plates seeded with *Escherichia coli* strain OP50 (ref. 2) is given in parentheses. The solid arrows represent moults. Moulting times were determined by monitoring pharyngeal pumping in synchronized populations¹². Wild-type dauer larvae obtained from starved populations initiate pharyngeal pumping 2–3 h after being placed in food. The moult to the L4 stage occurs after an additional 8 h. The 8-h time from egg to L1 is the interval between egg laying and hatching. The entire life cycle requires 3 days at 25°C.

Such stages of arrested development occur in other nematodes, and the similarity with the obligate (usually infective) form of many pathogenic parasites should not be entirely overlooked¹⁰.

In our genetic studies, we have isolated mutants of *C. elegans* of two kinds—'defective' mutants which do not produce dauer larvae even when starved¹¹, and 'constitutive' mutants which produce dauer larvae even with abundant food¹². The genes concerned are named *daf* (for 'dauer larva formation').

We have screened clones for defective mutants by treating nematodes with the mutagen ethyl methane sulphonate (EMS) and selecting clones of F₂ hermaphrodite progeny which do not form dauer larvae after starvation; a total of at least 15 genes is involved^{11,13}. We have obtained 38 constitutive mutants from nematodes treated with either EMS or DES (diethyl sulphate) by selection for dauer larvae with 1% SDS¹⁴.

Thirty-three of the constitutive mutants are *ts* (temperature-sensitive), while five are 'leaky' (incompletely penetrant) at all growth temperatures. The best of the *ts* mutants grow normally at 15°C, but all larvae grown at 25°C become dauers at the second moult. The dauer larvae cannot recover until the incubation temperature is shifted down to 15°C. The *ts* mutants are all recessive, and they define seven complementation groups (see Table 1). SDS selection can only yield conditional or leaky mutants which are able to recover and reproduce. The isolation of unconditional (non-recovering) dauer-constitutive mutants will be described elsewhere.

Epistatic ordering of genes

A relationship between constitutive and defective mutations was detected by selecting revertants of *ts* dauer-constitutives, *daf-2 daf-4* and *daf-7* (Table 2). Homozygous revertants, arising in the F₂ generation after mutagenesis, grow and reproduce at 25°C, while parental-type larvae become dauers and stop growing. Most revertants not only escape dauer formation, but they fail to form dauers even when starved. Crossing the revertants with the parental strain revealed that they were double mutants which carried not only the parental constitutive mutation, but also were homozygous for an epistatic, recessive dauer-defective mutation. Thus, some dauer-defective mutations can act as suppressors of dauer-constitutives.

Twenty-five independently isolated revertants were distributed among six complementation groups (Table 2) and some

revertants were alleles of dauer-defective genes which had already been genetically mapped (Fig. 3). To determine which dauer-constitutive mutants could be suppressed by various defectives, we constructed a series of multiple mutants by genetic crosses (Table 1). One interpretation of these data could be that constitutive and defective mutations produce competitive influences on dauer larva formation in a double mutant. The more extreme alleles might be epistatic to less extreme alleles, so that the cross-suppression tests rank the mutations quantitatively in order of severity. Several observations argue against this hypothesis as a general explanation for the observed interactions. First, there is no uniform gradient of suppression. For example, the *daf-12* mutation suppresses *daf-4* but not *daf-2* while the *daf-20* mutation exhibits the opposite pattern. Second, ranking the *ts* mutants by the degree of expression at intermediate temperatures does not produce a correspondence to the suppression pattern¹². Based on the degree of expression of the *ts* constitutive strains at a range of temperatures between 15 and 25°C, the *daf-7* strain was judged to carry the most severe *ts* allele, while the *daf-14* strain carries the least severe allele. Third, *daf-16* provides an absolute block to the most

Table 2 Origin of dauer-defective mutations

Gene and linkage group	Reference allele	No. of alleles collected*			Estimated mutation frequency
		By reversion†	Other‡		
<i>daf-10 IV</i>	<i>e1387</i>	—	—	2	5×10^{-4}
<i>daf-18 IV</i>	<i>e1375</i>	—	—	1	
<i>daf-17 I</i>	<i>m27</i>	—	—	5	1×10^{-4}
<i>daf-6 X</i>	<i>e1377</i>	—	—	1	
<i>daf-16 I</i>	<i>m26</i>	—	—	1	2×10^{-5}
<i>daf-20 X</i>	<i>m25</i>	—	—	2	5×10^{-5}
<i>daf-3 X</i>	<i>e1376</i>	5	2	—	3×10^{-4}
<i>daf-5 II</i>	<i>e1386</i>	7	2	—	5×10^{-4}
<i>daf-12 X</i>	<i>m20</i>	1	—	—	5×10^{-5}

* Complementation tests were performed by crossing homozygous or hemizygous dauer-defective males with dumpy (*dpy*) dauer-defective (*daf*) hermaphrodites. Starved populations derived from cloned, non-dumpy F₁ progeny were scored for the presence or absence of dauer larvae both visually and by SDS treatment^{11,13}. Populations arising from heteroallelic F₁ progeny do not form dauers. Complementation *daf* mutations, on the other hand, allow many dauers to be formed even though some homozygous dauer-defective progeny are segregated in the F₂ generation. Because homozygous *daf-10* males do not mate¹¹, heterozygous *daf-10/+* males were crossed with *dpy daf* hermaphrodites. In these crosses, half the F₁ progeny produce dauer-defective populations when the *daf* mutations are allelic.

† To obtain revertants of *ts* dauer-constitutive mutations, strains CB1372, *daf-7(e1372)III*; CB1364, *daf-4(e1364)III*; CB1370, *daf-2(e1370)III*; CB1368, *daf-2(e1368)III* and CB1391, *daf-2(e1391)III* were mutagenized with EMS (ref. 6). In each experiment 4 adult hermaphrodites were placed on each of 50 100-mm diameter Petri plates seeded with OP50 and allowed to produce about 200 F₁ progeny per plate. After an initial 6 days of incubation at 15°C, adult F₁ progeny were shifted to 25°C for an additional 4 days. Adult F₂ revertants were cloned and re-tested for growth at 25°C, and for the dauer-defective phenotype after starvation. To assure independence of the mutations, no more than one revertant clone from each plate was saved. Homozygous revertant males were backcrossed to *dpy daf* hermaphrodites. The appearance of dauer-constitutive cross progeny in the F₁ demonstrates the continued presence of the parental dauer-constitutive allele in the revertant strain, as well as the recessive character of the suppressing dauer-defective mutation. The dauer-constitutive alleles were then removed from the genetic background of each revertant by crossing the homozygous revertant males with strains carrying *dpy* markers closely linked to the constitutive locus. Doubly homozygous *dpy;daf* F₂ segregants which no longer carried the constitutive mutation were saved for complementation tests. The *dpy;daf* strains were again crossed with wild-type males to remove the *dpy* marker. In each case homozygous or hemizygous males derived from a non-dumpy, dauer-defective segregant were used for cross-suppression tests (see Table 1).

‡ Alleles *e1387*, *e1376* and *e1386* were obtained by cloning F₂ progeny of mutagenized N2 hermaphrodites as described elsewhere¹¹. All mutants were subsequently backcrossed and re-segregated before complementation and genetic mapping. The *daf-18(e1375)III* mutation was discovered in strain CB1062, *vab-3 X*, and removed from the *vab-3* background by crossing with wild-type males and re-segregating the unlinked *e1375* allele. The *e1377* mutant was isolated after EMS mutagenesis by Dr James A. Lewis. The frequency of mutation in each gene in standard conditions of EMS mutagenesis² was estimated by dividing the total number of mutants obtained (columns 3–6) by twice the number of F₁ broods examined.

Fig. 2 External morphological differences between an L2 larva (a) and a dauer larva (b) are shown by scanning electron micrographs of the nose. The field width in each micrograph is $7.2\ \mu\text{m}$. An internal plug which completely closes the mouth of the dauer (b) is revealed in transmission electron micrographs of transverse sections (not shown). The dauer larva is thinner than the L2, and has an increased specific gravity due to radial shrinkage of the body at the dauer-specific moult⁷. In preparation for scanning electron microscopy, larvae were fixed overnight in cold 3% glutaraldehyde in 0.1 M phosphate buffer, pH 7.1, and post-fixed for 6 h in cold 1% buffered OsO_4 . Specimens were dehydrated in a graded series of ethanol, critical point dried in CO_2 , mounted on copper adhesive tape and gold coated. Photographs were taken at 10 kV on a Jeol JSM-1 scanning electron microscope.

extreme (non-recovering) constitutive mutations, although it does not suppress *ts* alleles of certain constitutive genes (in preparation).

A functional sequence

The data suggest that there is an order to the functions controlled by the *daf* genes, and that the constitutive and defective mutations affect a common sequence. On the basis of the suppression patterns (Table 1) the pathway in Fig. 4 can be constructed with individual genes assigned to the control of sequential steps. If the constitutive mutants were simply blocked in entry to the L3 stage (see Fig. 1), while defective mutants were blocked in a separate sequence to the dauer larva, the constitutive-defective double mutants could not continue larval development at all. Instead, the data indicate that the dauer-defective mutants are blocked in the pathway to the dauer stage while the dauer-constitutives generate a false, internal signal which causes the mutants to form dauer larvae even in the absence of appropriate environmental cues. If the pathway is blocked after the false signal, a double mutant will be dauer-defective. However, if the false signal is generated after the block, a double mutant will be dauer-constitutive.

An unambiguous order of function can be assigned to most dauer-constitutive genes. However, *daf-2* seems to be in a distinct branch of the pathway. The *daf-16* and *daf-20* mutations suppress *daf-2* but not *daf-4*, while *daf-3*, *daf-5* and *daf-12* suppress all constitutives except *daf-2*. A block in the upper branch of the pathway is both necessary and sufficient to produce a dauer-defective phenotype. Therefore, we conclude that the lower pathway specified by *daf-2* does not function in these conditions. This second pathway may represent the response to different environmental signals, or it may function only in *daf-2* mutants.

Our goal is to establish specific behavioural or morphological correlates with the mutant steps in the pathway. Two steps, represented by *daf-10* and *daf-6*, are correlated with chemotaxis defects, and both mutants exhibit ultrastructural alterations¹¹ in specific neurones which have previously been implicated in the chemosensory response to salts^{15,16}. These dauer-defective mutants exhibit pleiotropic defects, both in chemosensory behaviour and in neuroanatomy. Nevertheless, ultrastructural evidence suggests that one or more amphidial neurones mediate a sensory signal for dauer larva formation¹¹. The amphids are a pair of sense organs consisting of 12 neurones, 8 of which extend afferent processes anteriorly to openings on the lateral sides of the mouth^{17,18}.

The genetic pathway may correspond to a neural pathway involved in detection of an environmental signal by sensory

receptors followed by transduction of the signal to neurosecretory cells. According to this hypothesis, neurosecretion would then alter the hormonal balance in the nematode to initiate dauer larva morphogenesis. The final step in the pathway may represent defects in the reception of the neurosecretory signal. Underlying the neural pathway would be the developmental processes which produce a functional set of nerve cells. For example, a mutation affecting morphogenesis of sensory neurones would affect the pathway at a position corresponding to that sensory function. Thus, we expect that many of the genes exert their primary effects on development well before the pathway is actually set in motion physiologically. This contention is supported by the results of temperature-shift and temperature-pulse experiments which define temperature-sensitive periods before the L2 stage for six of the *ts* dauer-constitutive mutants¹².

One or more steps in the pathway may involve amphid function. The *daf-6* mutant exhibits amphid defects as does *daf-10*, but other neurones in the *daf-6* mutant are also affected¹¹. None of the other mutations positioned in the pathway exhibits the behavioural abnormalities characteristic of the non-chemotactic dauer-defective mutants, *daf-6* and *daf-10*.

Fig. 3 Simplified genetic map of *C. elegans* showing the six linkage groups with *daf* loci labelled above the lines. Other markers used in mapping crosses and in cross-suppression tests (Table 1) are shown below the lines. Linkage relationships are as described previously²¹. Gene designations are *daf* (dauer larva formation), *dpy* (dumpy), *lon* (long) and *unc* (uncoordinated). The locations are shown only for mutations which have been unambiguously ordered. When two genes are joined at the same location, no recombination has been detected between them. The *daf-20* gene is X-linked, but is not shown because its location has not been determined.

Fig. 4 A simple genetic pathway for dauer larva formation, one of several possible representations, based on epistatic relationships between dauer-constitutive mutations and dauer-defective mutations. Gene names of dauer-constitutives are given in the pathway itself to represent points where false signals may be initiated. Mutations in dauer-defective genes block the pathway at the positions shown by dashed lines. The *daf-10* mutation is drawn to block both branches of the pathway on the basis of indirect evidence. First, both *daf-8* and *daf-2* are epistatic to *daf-10*, and second, the *daf-10* mutation blocks recovery of both *daf-2* and *daf-8* dauer larvae (see text).

However, if the gene order corresponds to a pathway of neurotransmission, electron microscopic analysis of *daf* mutants positioned near the end of the pathway may reveal anatomical defects in neurosecretory cells.

Genetic complexity of the pathway

C. elegans possesses three to four thousand essential genes^{2,19}. We estimate, based on mutation frequency and the fraction of new mutations which recur in previously characterized genes (in preparation), that there are ~100 genes affecting dauer larva formation. Dauer-constitutive mutants are rare, occurring at an aggregate frequency of 0.2% or about four times the mutation frequency per average gene in standard conditions of EMS mutagenesis^{2,13}. All seven of the constitutive genes detected by our mutant selection are represented by more than one allele. Therefore, we conclude that we are approaching saturation of the *ts* dauer-constitutive mutant class.

Two other experiments support this view. First, we have used dauer-defective mutants late in the pathway (*daf-16* and *daf-20*) as parent strains for selecting a restricted class of dauer-constitutive mutants which might define even later steps in the pathway (see Fig. 4). After mutagenesis with EMS or DES, the progeny of nearly 9,000 F₁ animals were screened. This population is of sufficient size to detect four or five alleles of the average gene in *C. elegans*. In fact, five new alleles of *daf-4* were found, but no new dauer-constitutive genes were identified. Second, mutants with maternal effects have not been overlooked. All eight alleles of *daf-1* share this property. Homozygous *daf-1* animals do not form dauer larvae if their maternal parent was heterozygous (+/*daf-1*). Selection for maternal-effect mutants (not expressed until the F₃ after mutagenesis) produced six new alleles of *daf-1*, but no other constitutive genes with a maternal effect.

Although the genetic evidence suggests that there may not be many more than 7 genes of the *ts* constitutive class, we estimate that there may be as many as 100 genes of the defective type¹³. It is likely that more defective genes will be positioned within the pathway, since four of the nine genes in the pathway are represented by only a single isolate (see Table 2) and other dauer-defective mutants have not been tested for their suppression properties. The frequency of dauer-defective mutants obtained by EMS mutagenesis of wild-type *C. elegans* is 5%. Many of these mutations may exert their effects indirectly as in the case of *daf-10* and *daf-6*, two mutations which affect neural development.

Other genes do not affect the signal, but do affect the subsequent process of dauer larva morphogenesis. For example,

a *daf-13* mutant forms apparently normal dauer larvae in response to starvation, but the dauers are sensitive to SDS treatment, possibly because of a defect in cuticle maturation (unpublished results). When the *daf-13* mutation is combined with the dauer-constitutive, *daf-2*, the constitutive phenotype is unaltered except that the constitutively formed dauer larvae are sensitive to SDS. We believe *daf-13* to be representative of a class of 'process' mutations which do not affect the signal pathway and do not exhibit epistatic interactions with dauer-constitutive mutations.

There are few, if any, genes which are involved specifically in exit from the dauer stage. Selection (by resistance to SDS) for mutants which are abnormally slow in dauer larva recovery produced no new mutant types. The only mutants found were dauer-constitutives (which recover slowly) and leaky dauer-defectives (affected in both entry and exit). This suggests that the genetic requirements for recovery from the dauer stage are similar to the requirements for entry. To determine if all dauer-defective genes specifying the entry pathway also affect exit from the dauer stage, we constructed the following three strains in which the constitutive gene, *daf-1*, is epistatic: *daf-1 daf-10*, *daf-1 daf-17* and *daf-1 daf-6*. In both the *daf-10* and *daf-6* double mutants, recovery of constitutively formed dauers (on temperature-shift to 15°C) is almost completely inhibited, showing that function of these genes is required for both entry and exit, but in the case of the *daf-1 daf-17* double mutant, dauer larva recovery is at most only marginally inhibited. Thus, the genes required for exit from the dauer stage may be simply a subset of the genes required for entry.

Dauer larva formation seems to be relatively unaffected by most of the animal's genes, allowing us to study this sequence in relative isolation from the rest of development. The properties of this system permit an unusual application of classical genetic methods to the analysis of a developmental pathway. Elucidation of the physiology of dauer larva formation will require further work to identify the specific molecules which act as environmental cues, the neurones involved in signal processing, what neurotransmitters these cells use and what hormones mediate the response. As a formal genetic problem, dauer larva development seems about as complex as that of bacteriophage T4 (ref. 20), and it is therefore a reasonable goal to characterize its genetic specification completely.

Left-handed DNA in restriction fragments and a recombinant plasmid

Jan Klysik, Steven M. Stirdivant, Jacquelyn E. Larson, Phillip A. Hart & Robert D. Wells

University of Wisconsin, Department of Biochemistry, College of Agricultural and Life Sciences, Madison, Wisconsin 53706, USA
and School of Pharmacy, University of Wisconsin, Madison, Wisconsin 53706, USA

Circular dichroism and ^{31}P -NMR on synthetic oligomers of (dC-dG) inserted within DNA restriction fragments indicate that the right-handed B-structure can exist in close proximity to the left-handed Z-structure. Also, this salt-induced transition to Z-form in a small (dC-dG) segment (1.3%) of a recombinant plasmid markedly influenced the supercoil of the plasmid. These observations have implications for the postulated role of naturally occurring related simple sequences in the regulation of gene activity.

DUPLEX DNA polymers and oligomers containing a strictly repeating dG and dC sequence have been known for some time to display unusual conformational properties¹. High molecular weight $(\text{dG-dC})_n \cdot (\text{dG-dC})_n$ has been synthesized² and characterized by a variety of biochemical and physical approaches (reviewed in refs 1, 3). The presence of high concentrations of salt (NaCl , NaClO_4 , MgCl_2) or ethanol causes this polymer, but not related synthetic polymers, to undergo a marked structural transition as revealed by circular dichroism (CD) and Raman spectroscopy⁴⁻⁷. This cooperative transition has more recently been interpreted (see below) as a conversion of the right-handed helix into a left-handed structure, an observation foreshadowed by the demonstration that $(\text{dI-dC})_n \cdot (\text{dI-dC})_n$ had a very unusual left-handed conformation at normal salt concentrations and could undergo a transition to a typical right-handed DNA-B conformation at high humidities⁸⁻¹⁰.

Recent X-ray crystallography studies on short oligomers $[\text{d}(\text{CpGpCpG})]$ and $[\text{d}(\text{CpGpCpGpCpG})]$ revealed the very unusual Z- and Z'-DNA conformations¹¹⁻¹⁵. The Z-conformation differs from the typical right-handed DNA-B structure in that the helix is left-handed with 12 base pairs per turn, the sugar conformations are not all the same but dG is C3'-endo and

dC is C2'-endo and the G residues are in a *syn*, not the orthodox *anti*, conformation. The Z-conformation may correspond to the high salt form of $(\text{dG-dC})_n \cdot (\text{dG-dC})_n$ with the 'inverted' CD spectrum¹¹, particularly as Raman spectroscopy of the crystals used for the X-ray analyses demonstrates the correlation with the high salt form of $(\text{dG-dC})_n$ (A. Rich, personal communication). Also, recent ^{31}P -NMR studies (refs 16, 17 and J. S. Cohen, personal communication) on oligomers with strictly alternating dG and dC residues demonstrates the salt-induced conformational transition from a typical phosphodiester structure (in low salt) to an alternating structure (in high salt). The alternating backbone conformation is presumed to be of the Z-type. It may be that, as proposed^{11,18}, any DNA with a perfectly alternating sequence of purines and pyrimidines adopts a Z-type conformation.

Z-type DNA in a natural genome

The relevance of these observations to natural DNA and their possible implications for the regulation of gene activity is still largely speculative. We therefore decided to construct a recombinant DNA in which poly(dG-dC) was cloned in restriction fragments of plasmid DNA. This approach, based on our

Fig. 1 DNAs used in these studies. pRW751 is a recombinant plasmid derived from pBR322 (ref. 29) which contains a 157-base pair (bp) insert into the 'filled in' *Bam*HI site. The cloning procedure, preparation of plasmid DNA and preparation and characterization of DNA restriction fragments were generally performed as previously described^{1,21,22,24,31}. The 157-base pair fragment was sequenced essentially as described elsewhere²³; the *Bam*HI ends were labelled with ^{32}P and the fragment was cleaved with *Hpa*II. The DNA sequence revealed the presence of the perfectly alternating (dC-dG) sequence shown in this figure along with the presence of the *lac* sequence. The localization of the 26- and 32-base pair (dC-dG) arms relative to the *lac* 95-base pair fragment is precisely known. However, the orientation of the entire 157-base pair insert with respect to the vector is not known. The polymer of the 157-base pair fragment was prepared by a large-scale T4 DNA ligase reaction with the 157-base pair monomer in conditions described previously²² using 100 μg of the 157-base pair fragment. The number average molecular weight (50-mer) of the polymers which resulted from this reaction was established by gel electrophoresis and, more rigorously, by spectrophotometric analysis of the RPC-5 chromatography used in the preparation of the 'inside-out' 157-base pair fragment. This fragment was prepared by *Hpa*II cleavage of the polymer of the 157-base pair fragment. The 'inside-out' molecules are, in fact, a mixture consisting of fragments which are 138, 157 and 176 base pairs long. This mixture was purified from the 'half molecules' (70 and 87 base pairs in length) which were derived from the termini of the polymer. Gel electrophoretic analysis of the purified 'inside-out' 157-base pair molecules showed no detectable 'half molecules' (<1%). The 220-base pair fragment was isolated from pRW751 by a three-step procedure; first, 6 mg of pRW751 were digested with *Hind*III and the resulting products were separated on a preparative polyacrylamide gel. The 780-base pair fragment was extracted from the gel and cleaved with *Taq*I + *Hae*III and the products of this digestion were then fractionated on a preparative polyacrylamide gel. The 220-base pair fragment was extracted from the gel and further purified by column chromatography on DEAE-Sephacel (0.5 $\times$ 0.5 cm) in 10 mM Tris-HCl (pH 7.6), 0.1 mM EDTA. The column was washed with 3 ml of the same buffer and the 220-base pair fragment was eluted with 2.0 M NaCl in 10 mM Tris-HCl (pH 7.6) and 0.1 mM EDTA. The orientation of the 37- and 26-base pair segments of pBR322 on the termini of this molecule relative to the 157-base pair segment was not determined. pBR322 segments are designated with cross-hatching.

Fig. 2 Circular dichroism spectra of the 157-base pair fragment. The solid lines show the spectra of the 157-base pair fragment in 1.0 and 5.0 M NaCl. The dotted lines show the calculated spectra for a mixture of the *lac* 95-base pair fragment and $(dG-dC)_n \cdot (dG-dC)_n$ at the same molar ratio as in the 157-base pair fragment. The 1.0 and 5.0 M NaCl spectra for the *lac* 95-base pair fragment as well as for the $(dG-dC)_n \cdot (dG-dC)_n$ were taken separately. A solution of $(dG-dC)_n \cdot (dG-dC)_n$ was equilibrated for 4 h at room temperature before the spectra were determined. The extinction coefficients used were the following: *lac* 95-base pair fragment, 6.5×10^3 ; $(dG-dC)_n \cdot (dG-dC)_n$, 7.1×10^3 ; the 157-base pair fragment, 6.7×10^3 . The inset shows the influence of salt concentration on the CD at 295 and 250 nm. The spectra at the different salt concentrations were obtained by diluting the 5.0 M NaCl solution of the 157-base pair fragment with 10 mM cacodylate buffer (pH 7.2) and 0.1 mM EDTA. After each dilution, the sample was equilibrated for 0.5 h at room temperature before the CD spectra were determined. The equilibration time for this fragment was very short; 95% of the transition was obtained after 7 min. $(dG-dC)_n \cdot (dG-dC)_n$ was synthesized as described previously^{2,10}. The *lac* 95-base pair fragment was also prepared and characterized as described previously²⁵ (gift of W. Hillen). All details regarding the CD measurements are described elsewhere²⁵.

methods of cloning^{19,20} and characterizing²¹ other types of DNA polymers with simple sequences, was designed to allow the study of several important questions regarding the Z-structure, including the following: (1) Can Z-DNA exist between flanking segments of B-DNA? (2) What length of (dG-dC) is required to provide a stable Z-conformation? (3) What are the nature and length of the junction between the Z-DNA segments and the flanking B-regions? (4) To what extent does the left-handed Z-type structure influence the biological and physicochemical properties of the neighbouring sequence of random DNA (B-structure) or vice versa? (5) As a Z-type conformation is left handed, does a B $\rightarrow$ Z transition influence the tertiary structure (supercoil) of a plasmid molecule, and will the presence of supercoiling alter the environmental conditions necessary to stabilize a Z-type conformation? (6) Do some biological molecules, such as proteins or small ligands (drugs or carcinogens), specifically interact with the Z-form?

$(dG-dC)_n$ in a plasmid and restriction fragments

Figure 1 illustrates several of the molecules used in this study. A recombinant plasmid (pRW751) was constructed containing an insert 157 base pairs long which was generated by ligating the 95-base pair *lac* operator-promoter fragment²² with a mixture of oligomers prepared by digestion of $(dC-dG)_n \cdot (dC-dG)_n$ with *Fnu*DII. This mixture was ligated into the 'filled-in' *Bam*HI site

of pBR322 by the general procedures described previously^{1,20-22}. The preparation and characterization of this family of recombinant DNAs will be described in detail elsewhere (J. K. and R. D. W., in preparation). A large number of related plasmids were isolated and characterized, many of which were unstable; deletions were observed in the (dC-dG) segments for plasmids which contained (dG-dC) tracts longer than about 40 base pairs (discussed below), but stability was achieved with shorter (dG-dC) tracts. One such plasmid (pRW751) was chosen for further study. It has the structure shown in Fig. 1 and a 157-base pair fragment, excised from it by *Bam*HI and sequenced by methods described previously²³, was shown to consist of the 95-base pair *lac* fragment flanked by strictly alternating dC and dG sequences.

Figure 1 also shows the structure of a polymer of the 157-base pair fragment. This polymer was prepared to internalize the (dC-dG) segments and so evaluate the role of free ends in any possible transition observed in the 157-base pair fragment. The presence of the *Bam*HI sites on the termini of the 157-base pair fragment allowed the formation of this polymer. The polymer was characterized by *Hpa*II digestion followed by quantification of the 'inside-out' 157-base pair fragment relative to the amount of 'half molecules' which are derived from the polymer termini (see below).

Since the first 50-mer of the 157-base pair fragment still contained a small amount of (dC-dG) sequence at the termini, it could not be used to determine rigorously whether the structural transition from a B- to a Z-type structure had to be initiated by (dC-dG) segments at the ends of a DNA molecule or whether it was possible for a segment of (dC-dG) in the interior of a natural sequence to undergo the transition. We therefore produced the inside-out 157-base pair fragment shown in Fig. 1 by *Hpa*II digestion of the 157-base pair 50-mer. This molecule was purified by HPLC on RPC-5 (ref. 24) which cleanly separated the 157-base pair fragment from the small amount of half molecules. Hence, with the inside-out 157-base pair fragment,

Fig. 3 36.44 MHz ^{31}P -NMR spectra of the 157-base pair fragment in 0.5 and 5.0 M NaCl. The spectra represent a fast Fourier transformation of 4,096 time domain points accumulated following a 90° observing pulse and a 4.2-s delay. Proton resonances were fully and continually decoupled. Exponential multiplication resulting in 0.5 Hz line broadening was applied. Integration was done automatically from manually selected regions of the line integral display. The displayed signals are upfield relative to external 0.95 M H_3PO_4 ; no corrections for salt effects on the deuterium lock signal were made. Temperature was $25 \pm 0.2^\circ\text{C}$. a, 2 mg 157-base pair fragment per ml in D_2O , 0.5 M NaCl, 10 mM cacodylate buffer pH 7.6 and 0.1 mM EDTA; 14,000 accumulations. b, 2 mg 157-base pair fragment per ml in D_2O , 5.0 M NaCl, 10 mM cacodylate buffer pH 7.6 and 0.1 mM EDTA; 19,000 accumulations. The area of the downfield and smaller signal is $\sim 20\%$ of the total resonances. The greater line width at high salt in the 157-base pair fragment could be due to the larger viscosity of the concentrated salt solution, paramagnetic impurities or intermediate phosphorous conformations.

Fig. 4 Circular dichroism spectra of the inside-out 157-base pair fragment in 2.8 and 5.0 M NaCl. The inset shows the CD changes observed at 250 and 295 nm as a function of salt concentration. Other details are described in the legends to Figs 1 and 2.

no (dC-dG) segments are on the termini. It is actually a random mixture of three molecules 138, 157 and 176 base pairs in length which is generated by the *in vitro* ligation used in forming the 50-mer. Note that the (dG-dC) segment in the inside-out 157-base pair fragment contains the *Bam*HI site in its interior.

These three fragments contain identical sequences but in different arrangements. One additional derivative of pRW751 that we have studied is a 220-base pair fragment consisting of the 157-base pair fragment, flanked by segments of pBR322 DNA, 37 and 26 base pairs long (Fig. 1). Hence, the (dC-dG) sequence is flanked by natural sequences which are longer than those for the inside-out 157-base pair fragment. Studies on this 220-base pair fragment supplemented studies with the 50-mer and the inside-out 157-base pair fragment designed to determine if the GATC sequence would adopt a Z-type structure or would remain in a B-conformation in high salt. The 220-base pair fragment differs from the other two DNAs in having (dC-dG) tracts which are uninterrupted by GATC.

Z-type DNA in the 157-base pair fragment

Figure 2 shows the spectra for the 157-base pair fragment in 1.0 and 5.0 M NaCl. In addition, the calculated spectra are shown in identical conditions for the mixture of the appropriate molar ratio of (dC-dG)_n · (dC-dG)_n and the purified 95-base pair fragment. In 1.0 M NaCl, the 157-base pair fragment shows a typical spectrum observed for DNA restriction fragments²⁵; there is very close agreement between the observed spectrum and the spectrum calculated for the component parts. However, in 5.0 M NaCl, the spectrum changes markedly, with negative CD bands at 293 and 245 nm and a positive band at 268 nm. This spectrum agrees well in shape with a calculated spectrum but is lower in amplitude at the peaks at 293 and 268 nm (but not at 245 nm). This general shape in high salt is a result of a marked change in the CD spectrum for (dG-dC)_n · (dG-dC)_n (refs 4-7). The discrepancy between the observed CD curve at 5.0 M NaCl and the calculated curve indicates that a portion of the (dC-dG) arms does not undergo the salt-induced transition to the Z-type conformation (discussed below). Also, we conclude that most (perhaps all) of the 95-base pair *lac* segment remains in a B-structure.

The inset in Fig. 2 shows the cooperative nature of the change in CD at 295 and 250 nm as expected for the salt-induced B → Z

change in conformation in the (dC-dG) arms. In contrast, no cooperative change is observed in similar conditions for the 95-base pair *lac* fragment alone. The midpoint of this transition (~3.6 M) is substantially higher than for (dG-dC)_n · (dG-dC)_n (~2.5 M)⁴, presumably due to the junction with the *lac* sequence.

³¹P-NMR studies were performed to confirm that the inversion in the CD spectrum was due to formation of a Z-type conformation in the (dC-dG) ends of the 157-base pair fragment. Figure 3 shows the spectra observed in 0.5 and 5.0 M NaCl. A single symmetrical peak is observed in the lower salt whereas a second resonance, which is 1.45 p.p.m. downfield from the main resonance, was observed in 5.0 M salt. This result is clearly consistent with previous observations^{16,17}, which documented a splitting of similar magnitude in the phosphorous spectrum of the high salt form of (dG-dC)_n · (dG-dC)_n oligomers.

Integration of the peaks in Fig. 3b indicates that approximately 20% of the phosphorous resonances are in the second small peak which was shifted 1.45 p.p.m. As the (dG-dC) segment comprises ~37% of the 157-base pair fragment, this suggests that virtually all the (dC-dG) tracts have converted to a Z-type conformation. The finding that the NMR studies indicate transition of a larger percentage of the (dC-dG) sequences than is deduced from the CD measurements, may be due to the fact that different conformational features of the molecule are being investigated.

Laser Raman spectroscopy studies (in collaboration with R. M. Wartell) are in complete agreement with these results.

Z-type DNA between flanking B-DNA segments

Figure 4 shows the spectra observed in 2.8 and 5.0 M NaCl for the inside-out 157-base pair fragment. This molecule is of interest because the (dG-dC) segments are totally embodied within the 157-base pair fragment; there are no (dG-dC) segments at the termini.

A typical DNA spectrum²⁵ is observed for this fragment in 2.8 M NaCl. However, in 5.0 M salt the spectrum changes substantially. The trend of the changes is in agreement with the changes found for the 157-base pair fragment (Fig. 2) but their magnitude is less than observed for the 157-base pair fragment and less than calculated for the mixture of the 95-base pair *lac* fragment and the (dC-dG) arms. Thus, the two junctions of the (dG-dC) segments (at the *lac* fragment junctions and at the *Bam*HI site) clearly diminish the capacity of the (dG-dC) segment to undergo the B → Z conformational change. The inset in Fig. 4 shows that the observed transitions are cooperative, as expected for the B → Z conformational transition.

Two other fragments were studied which contained (dC-dG) segments between two naturally occurring B-DNA segments. The polymer containing an average of 50 tandem copies of the 157-base pair fragment (Fig. 1) was also studied by CD. This fragment differs from the inside-out 157-base pair molecule in length but not sequence. The CD spectra of this polymer at 2.8 and 5.0 M NaCl (data not shown) are almost identical to those shown in Fig. 4 for the inside-out 157-base pair fragment. Also the transition is cooperative, with a midpoint which is identical to that found for the inside-out 157-base pair fragment (3.9-4.0 M). Thus, the length of the molecule has no apparent influence on these properties.

Moreover, the CD properties of the 220-base pair fragment (Fig. 1) show the same trends as observed for the inside-out 157-base pair fragment and for the polymer of the 157-base pair fragment, but the magnitude of the change is somewhat less, as expected from its smaller (dC-dG) content. The quantitation of these transitions and their interpretation regarding DNA structure are described below. Because the same type of CD transition is observed with the 220-base pair fragment, we conclude that the transition is not a function of some peculiarity of the other three fragments (157-base pair, polymer of 157-base pair,

and inside-out 157-base pair fragments) but is a general property of the (dC-dG) sequence embodied in a natural DNA molecule.

Junction between B- and Z-type conformations

It is possible to calculate the fraction of the (dC-dG) segments which are in a Z-type conformation for all the fragments studied (Fig. 1), as virtually no CD signal at 295 nm is observed in 5.0 M NaCl for the *lac* 95-base pair fragment. Hence, any negative signal observed for the fragments at 295 nm must be due to (dC-dG) segments which are transformed into the Z-type conformation. Thus, by comparison with the calculated CD signal for the component parts, we can determine the amount of Z-type structure. For these calculations, we shall use an average of 29 base pairs for the (dC-dG) tracts (average of 26 and 32). For the 157-base pair fragments, we deduce that 65% (or 19 out of an average of 29 base pairs in each segment) are in a Z-type conformation. As each (dC-dG) segment is joined only once to the *lac* 95-base pair segment, 10 base pairs are in a conformation other than Z-type. We believe that these are at the junction of the (dC-dG) segment and the *lac* 95-base pair fragment.

For the inside-out 157-base pair fragment, 36% (or 10 base pairs out of an average length of 29) are in a Z-type conformation. As the (dG-dC) segment interfaces at both ends with a random type sequence, $19/2 = 9.5$ base pairs (or 10 base pairs) constitute the junction region. This, of course, presumes that the GATC *Bam*HI site disrupts the Z-type conformation of the (dG-dC) tract.

For the polymer of the 157-base pair fragment, 14% (or 4 base pairs out of an average of 29) are in a Z-type conformation. As the (dC-dG) region in this polymer also interfaces at both ends with random DNA sequences, $25/2 = 12.5$ base pairs constitute each of the junction regions which are not in a Z-type conformation. Similarly, for the 220-base pair fragment, 16% (5 base pairs out of an average of 29) are in a Z-type conformation, leaving a junction region of 12 base pairs.

Thus, the length of the junction regions for all four molecules ranges from 9.5 to 12.5 base pairs. The remarkable consistency in the length of this region implies the necessity for a transition region of ~ 11 base pairs from a B-conformation to the Z-type structure. The structure of this intermediate region (approximately one turn of helix) is unknown. Wing *et al.*²⁶ have determined the crystal structure of d(CGCGAATTCGCG); their finding that the CGCG termini are not in a Z-structure is consistent with our results.

These calculations make several assumptions, including the following: (1) The CD signal from the segments of *lac* and pBR322 DNA in these restriction fragments is the same as for the 95-base pair segment alone. That is, the conformation of the natural sequences as judged by CD is not influenced by their junction to Z-type DNA. (2) The GATC which comprises the *Bam*HI site is not in a Z-type conformation when the surrounding (dC-dG) tracts are in a Z-type structure for the cases of the polymer of the 157 base pairs and the inside-out 157-base pair fragment. (3) The junction regions (9.5–12.5 base pairs in length) of (dC-dG) residues which are not in a Z-type conformation give no CD signal at 295 nm.

Z-DNA in a supercoiled plasmid

It was of interest to determine if a Z-type conformation can exist within a covalently closed and circular DNA. On the basis of previous studies on supercoiled DNA, it is logical that a B $\rightarrow$ Z transition in a (dC-dG) segment should alter the number of supercoil turns in a plasmid DNA because the supercoil number is dictated by the specific linking difference which is sensitive to conformational changes in the primary helix (reviewed in refs 27, 28).

pRW751 was a suitable molecule for studying this question. The total length of (dC-dG) sequences in pRW751 is 58 base

pairs or 1.3% of the length of the total recombinant plasmid (4,516 base pairs). The unwinding of one turn of primary helix removes one right-hand supercoil. In addition, each turn of left-handed primary helix which is induced will also remove one right-hand supercoil. Thus, we can calculate that a complete transition of 58 base pairs of (dC-dG) from B $\rightarrow$ Z would theoretically remove 10.3 supercoils from pRW751 ($58/10.4$ base pairs per turn + $58/12$ base pairs per turn = 10.3).

We have established conditions for running agarose gels in NaCl solutions up to 5.0 M (Fig. 5) to determine the number of supercoil turns in a DNA. pRW451 served as a control for these electrophoresis experiments as it is identical to pRW751 apart from containing a 174-base pair insert (formerly a *Hha*I fragment of pBR322 DNA which contains 54% G + C) instead of the 157-base pair insert in pRW751. This 174-base pair insert does not contain unusual sequence features or stretches of (dC-dG) sequence²⁹.

Figure 5 shows the gel electrophoresis patterns observed for pRW451 and pRW751 in 3.0 and 4.5 M NaCl. In 3.0 M, the partially relaxed family of topoisomers for both DNAs comigrate (lanes a and b). For both DNAs in these electrophoresis conditions, the family ranges from approximately five right-

Fig. 5 High salt gels on supercoiled plasmids. Monomeric supercoiled pRW751 was separated from higher forms (such as dimer, tetramer) by HPLC on RPC-5 using a 1.5 mm $\times$ 20-cm column at 43 °C. Elution was with a 0.65–0.8 M KCl gradient using the general techniques described previously²⁴. pRW451 contains the 174-base pair *Hha*I fragment from pBR322 cloned into the filled-in *Bam*HI site of pBR322 (G. D. Staffeld and R. D. W., unpublished). pRW451 was isolated in a similar manner. Partially relaxed pRW751 and pRW451 were prepared by treatment with wheat-germ topoisomerase (gift of R. R. Burgess). Reaction mixtures (100 μ l) contained 20 μ g DNA and 8 μ g enzyme in 50 mM Tris-HCl pH 7.6, 0.1 mM dithiothreitol, 10 mM MgCl₂ and 2.5 mM spermidine. The reaction was for 30 min at 37 °C which gives a terminal reaction product of right-handed supercoiled topoisomers. The unrelaxed and partially relaxed plasmids were electrophoresed through 1% agarose gels with a buffer of 80 mM Tris-HCl, 40 mM sodium acetate, 4.4 mM disodium EDTA and 0.525 M acetic acid, all at pH 8.3, plus either 3.0 or 4.5 M NaCl. The gels were 8 cm $\times$ 14 cm $\times$ 1 mm. The DNA samples were equilibrated in a loading buffer identical to the electrophoresis buffer but with an identical molarity of NaClO₄ substituted for NaCl and 0.05% bromophenol blue added. The gels were electrophoresed for 36 h at 25 V for the 4.5 M NaCl gel and 20 V for the 3 M NaCl gel. The gels were desalted by soaking in water for 10 min and then stained with 100 μ g ml⁻¹ ethidium bromide. Abbreviations are: UM, unrelaxed monomer; N, nicked monomer; UD, unrelaxed dimer; RD, relaxed dimer. The following samples were electrophoresed in the designated lanes: a, partially relaxed pRW751; b, partially relaxed pRW451; c, unrelaxed pRW751; d, unrelaxed pRW451. Resolution of fully relaxed plasmid from supercoiled DNA containing +1 or -1 supercoils is difficult in these conditions. Similarly, the logarithmic nature of topoisomer migration prevents the resolution of individual bands for topoisomers containing ~ 10 supercoils.

handed supercoil turns to fully relaxed DNA (the exact number of supercoil twists is uncertain due to our inability to resolve topoisomers near the fully relaxed position, but we believe that this number is accurate within at least ± 1). This experiment was performed with plasmids which were partially relaxed with topoisomerase to obtain better resolution of the family of topoisomers and thus enhance our ability to detect smaller changes in supercoil number. Figure 5, lanes *c* and *d*, shows that the unrelaxed plasmids co-migrate in 3.0 M NaCl.

When similar studies were done in 4.5 M NaCl, no change was observed for the migration pattern of the partially relaxed control plasmid (pRW451) (Fig. 5, lane *b*). However, Fig. 5, lane *a*, shows that all the topoisomers for pRW751 co-migrated in these conditions at the fully relaxed position. Thus, a loss of as many as five supercoil turns was observed, but there was no apparent generation of left-handed supercoil twists.

This striking result clearly demonstrates that a salt-induced structural change occurred in pRW751 which had a dramatic influence on the supercoil number, and is consistent with a conformational transition from B- to a Z-type structure for at least a portion of the (dC-dG) tracts in pRW751.

A small difference was observed in the migration of pRW451 and pRW751 at 4.5 M NaCl (Fig. 5, lanes *c*, *d*). Based on our experience with topoisomer migration patterns, we believe this difference is equivalent to a loss of four to eight supercoil turns. However, the relatively poor resolution of topoisomers of high superhelical density makes precise quantification difficult, especially in these electrophoresis conditions.

Electrophoresis studies were performed on the partially relaxed plasmids at several salt concentrations between 3.5 and 4.0 M in addition to those shown in Fig. 5 to determine the degree of cooperativity. At salt concentrations of 3.5 M to at least 4.0 M, the topoisomers with more supercoil turns decreased in supercoil number at lower salt concentrations than topoisomers with fewer supercoil turns, suggesting that supercoiling contributes a favourable free energy to the B- to Z-type transition.

Thus, the studies with both the partially relaxed and unrelaxed plasmids indicate an unwinding of about five supercoil turns (conceivably not fewer than four and not more than eight) in 4.5 M NaCl. In the calculations described above, if the entire (dC-dG) segment in pRW751 converted from a B $\rightarrow$ Z conformation, we should have observed a loss of 10.3 supercoil turns. As this large an effect was not observed, the entire length of the (dC-dG) segments may not be in a Z-type structure, as predicted from the CD results.

Conclusions

Circular dichroism and ^{31}P -NMR studies on fragments show that the (dC-dG) segments undergo a cooperative transition to a left-handed conformation in the presence of high salt. The natural sequences from the *lac* operon and pBR322 do not appear to convert to a left-handed conformation. In all cases a junction of ~ 11 base pairs seems to exist between the left-handed conformation and B-DNA which is in neither a Z-type nor a B-conformation but must be intermediate in nature.

Moreover, electrophoretic analyses of plasmids containing the (dG-dC) sequence demonstrate a cooperative transition from a right-handed conformation to a left-handed Z-type structure. The presence of the (dG-dC) segment in the amount of 1.3% of the recombinant plasmid is sufficient to have a profound influence on the supercoil properties of the DNA. These observations are consistent with prior determinations on the extreme flexibility of the DNA chain (see ref. 30, reviewed in ref. 1).

Recombinant plasmids related to pRW751 commonly showed deletions in the (dG-dC) tracts, a type of behaviour unprecedented in our experience with a substantial variety of cloning studies^{1,19-22,24,31-33}. It seems that (dG-dC) segments longer than ~ 40 base pairs may not be stable in *Escherichia coli* (J. K. and R. D. W., unpublished).

Biological implications of left-handed DNA

The demonstration that different segments of one DNA chain can co-exist with conformations as different as a right-handed B-helix and a left-handed Z-type structure may have profound implications for the role of DNA structure in regulatory processes. Whereas this is not the first implication of DNA conformations and properties as important components in gene regulation or of left-handed DNA structures (reviewed in ref. 1), it is the first clear demonstration of left-handed DNA which is adopted by a naturally replicating molecule and by portions of restriction fragments isolated from that plasmid.

A segment of left-handed DNA in a viral or cellular DNA which is principally comprised of right-handed conformations would be an easily recognizable locus for binding of specific proteins or ligands³⁴ due to the dramatic difference in conformation. Moreover, the short region (approximately one turn of helix) at the interface between the B- and Z-conformations probably consists of intermediate structures which would also provide unique interaction contacts for ligand binding.

Our studies demonstrate that changes in the conformation of the primary helix in as little as 1.3% of pRW751 can profoundly influence its supercoil structure. Thus, conformational transitions in tiny portions of a chromosome can have large effects on the overall topography of a genome. As the extent of supercoiling has differential effects on the transcription properties of different genes (reviewed in ref. 1), this implicates conformational transitions in the primary helix as a genetic regulatory mechanism.

Our results clearly demonstrate that the cooperative salt-induced transition can be initiated within a polynucleotide chain. It is possible that a smooth and nondisruptive transition may be sterically and energetically feasible between B- and Z-conformations, as shown³⁵⁻³⁷ for the interface of B- and A-structures.

It is uncertain if appropriate natural sequences, in fact, undergo a transition to a Z-structure *in vivo*. However, several microorganisms (for example, halobacteria) as well as crustacea have high intracellular salt concentrations. Moreover, agents other than high salt may effect the B $\rightarrow$ Z transition *in vivo*.

Do sequences exist in viral or cellular DNAs which can adopt a left-handed conformation? We are unaware that a long tract of perfect (dG-dC) has yet been found in a duplex DNA. However, 7-base pair lengths of this sequence are found in a hairpin region of four related parvovirus genomes (reviewed in ref. 1). Moreover, a number of related repeating dinucleotide sequences have been found³⁸⁻⁴³.

Evolution of the 87A and 87C heat-shock loci in *Drosophila*

A. J. Leigh Brown & D. Ish-Horowicz

Imperial Cancer Research Fund, Mill Hill Laboratories, Burtonhole Lane, London NW7 1AD, UK

Several species related to Drosophila melanogaster have two loci containing sequences which code for the major heat-shock protein of molecular weight 70,000 (hsp70). These sequences are arranged as two pairs of inverted repeats. The structure of the 87C locus in D. melanogaster seems to have arisen through DNA insertion. Hsp70-coding sequences at the two loci are not evolving independently. Gene conversion between hsp70 genes has apparently occurred both within and between loci.

In higher eukaryotes, a single enzymatic function is frequently encoded at more than one locus. The duplicated loci need not be closely linked but are likely to derive from a single ancestral locus. A second form of gene reiteration is the presence of tandem arrays of repeated genes, for example ribosomal DNA and 5S genes. We have studied the evolution in *Drosophila* of a gene system showing both styles of duplication for which detailed molecular analysis is possible. Several features have emerged which suggest that classical views on mutation and evolution in such systems are inadequate.

Exposure of *Drosophila* tissue to a temperature of 37 °C activates a characteristic set of about nine chromosomal puffs and also induces the synthesis of a new set of about nine proteins (reviewed in ref. 1). As the heat shock inhibits previous RNA and protein synthesis, the resulting pattern of macromolecular synthesis is greatly simplified. Several laboratories have used heat-shock mRNA to select cloned genomic DNA fragments that encode the major 70,000-molecular weight heat-shock protein (hsp70). Such DNA fragments have been localized to two heat-induced puffs (87A and 87C)^{2–4}. This has been confirmed by genetic analysis using mutations that delete one or other locus. In this way, the two hsp70-coding loci were mapped to the single bands 87A7 and 87C1 (ref. 5). The sibling species

Drosophila simulans also makes a 70,000-molecular weight heat-induced protein⁶, and *in situ* hybridization shows that it too is encoded at two loci, 87A and 87C (ref. 2). A second type of heat-induced sequence, called 'αβ' sequences, is found at 87C1 but not at 87A7 in *D. melanogaster*⁷. These sequences seem to be absent at both hsp70 loci in *D. simulans*, although, like *D. melanogaster*, they are found at the chromocentre².

The arrangement of hsp70-coding sequences in *D. melanogaster* has been elucidated by use of cloned DNA sequences. The total number of hsp70 genes varies from five to about eight according to genotype, there being two copies at 87A7 and three to five at 87C1 (refs 8–10). (In this discussion, 'gene' refers to an mRNA-coding element and adjacent conserved sequences. 'Locus' designates the cytogenetic origin, that is, 87A7 or 87C1.) Each of the hsp70 genes seems to be organized within a 2.5-kilobase conserved element (z), comprising the 2.1-kilobase mRNA-coding region (z_c) and the 400 5'-terminal bases that are not transcribed (z_{nc})^{3,8,9,11}. Nevertheless, the z elements at 87A7 and 87C1 differ by some characteristic restriction sites^{8,10}.

Studies on gene arrangement at the hsp70 loci have shown that the two hsp70 genes at 87A7 are about 1.7 kilobases apart (Fig. 1) in an opposite orientation^{9,12,13}. The copies at 87C1 are

Table 1 Comparison of 87A and 87C heat-shock loci in *D. melanogaster*, *D. simulans* and *D. mauritiana*

Division of the hsp70 genes into protein-coding and non-protein-coding regions was made from ref. 35. The protein-coding region includes the 3'-terminal *SalI* sites and the 5' *BglII* sites. It does not include the 5' *PstI*, *SalI* or *EcoRI* (*D. mauritiana*) sites. The total number of restriction sites is the number of sites in one species which could have been detected in a second. This number varies in different comparisons because only the restriction sites closest to the z elements could be mapped. The mean frequency of nucleotide substitution and its variance (Var δ) were estimated after Nei and Li⁴².

Fig. 1 Organization of hsp70-coding loci. DNA extraction, purification, digestion and electrophoresis were as described previously^{8,13}. DNA was prepared from adult flies of inbred strains of *D. simulans* and *D. mauritiana* obtained by single pair matings for several generations. The DNA was analysed by the technique of Southern¹⁵ as adapted by Wahl *et al.*⁴³. The organization of hsp70-coding loci in *D. melanogaster* is redrawn from ref. 13. (The region depicted in the inset at the 87C1 locus is not drawn to scale.) The hsp70-coding sequences in our inbred strains of *D. simulans* and *D. mauritiana* were positioned and oriented at the cytogenetic loci using two locus-specific probes. Plasmid 56H8/C is derived from plasmid 56H8 (ref. 16) and contains a subcloned *SalI*-*EcoRI* fragment that lies just downstream of the distal hsp70 gene at 87A7. This probe hybridizes only to restriction fragments of *D. melanogaster* known to come from 87A7 (data not shown). It allows us to visualize restriction fragments from 87A7 and to orientate the 87A7 restriction maps on the chromosome. Similarly, plasmid S2A is derived from a cosmid clone cHS2 bearing two tandem genes from the distal region at 87C1 in *D. melanogaster* (A. Udvardy, personal communication). We have subcloned the *SalI*-*EcoRI* fragment immediately downstream from the most distal *z* element of cHS2, making a probe specific for 87C1. The *z* elements whose 3'-adjacent DNA sequences hybridize to these probes are aligned in the figure. Note that the designation of the homologous genes as 'proximal' and 'distal' is inappropriate in *D. simulans* and *D. mauritiana* because of the large inversion on this arm of the third chromosome which is found in these species¹⁴. To avoid confusion only the *D. melanogaster* restriction maps have been thus labelled. kb, Kilobase.

present in two domains, a single proximal sequence separated from tandem distal sequences by about 38 kilobases containing the $\alpha\beta$ heat-induced sequences¹³ (Fig. 1).

In this article we compare the gene organization of hsp70 sequences in three closely related species, *D. melanogaster*, *Drosophila mauritiana* and *D. simulans*, which show very similar polytene chromosome banding patterns¹⁴. We deduce the probable ancestral organization, and use the restriction maps to estimate the frequency of nucleotide substitution between the species. We also find that the hsp70 genes within a species are much more alike than would be expected if they were evolving independently. This suggests that there is gene conversion both within and between hsp70 loci and we discuss a possible mechanism by which this could occur.

Organization of hsp70-coding sequences in *D. simulans* and *D. mauritiana*

Hsp70 genes of *D. simulans* and *D. mauritiana* are found at two loci, 87A and 87C, as in *D. melanogaster* (ref. 2; S. M. Pinchin, personal communication). We have studied their organization in adult fly DNA using the transfer hybridization method of Southern¹⁵. Figure 1 shows the restriction maps of the hsp70 loci of *D. simulans* and *D. mauritiana*. The maps reveal that the hsp70-coding regions lie within a conserved z element, as in *D. melanogaster*. In particular, the *Xba*I and *Xho*I restriction sites characteristic of z_{nc} are conserved, strengthening the idea that z_{nc} is important for hsp70 expression³. In Fig. 2 we show certain restriction digests that establish the conservation of z elements and others that demonstrate the presence of four coding sequences in these species. Our *D. simulans* and *D. mauritiana* stocks did not show the variation in hsp70 gene number that is found in *D. melanogaster*, but we have not examined other independent lines.

Both hsp70 loci of *D. simulans* and *D. mauritiana* have the same organization—two hsp70 genes in opposite orientations (Fig. 1). We have demonstrated the presence of inverted-repeat hsp70 genes by the presence of S_1 nuclease-resistant genes in denatured genomic DNA (Fig. 2C). We find two S_1 -resistant ('snapback') bands of 2.6 and 2.8 kilobases which include the whole z element. [The absence of an *Xho*I site in an 87C gene of *D. mauritiana* is due to a restriction site polymorphism (A.J.L.B., unpublished data).] This orientation is confirmed by digestion of chromosomal DNA with the restriction enzyme *Sac*I which cuts every hsp70 gene near the 3' end^{4,13}. Only a single 5.3-kilobase band is found (Fig. 2C), showing that the genes are paired and the same distance apart.

Fig. 2 A, Hsp70 genes are arranged in a z element in *D. mauritiana* and *D. simulans*. Autoradiograms of transferred agarose gels were hybridized with the plasmids pPW232.1 and pPW229.1, probes for the 5' and 3' halves of the hsp70 gene respectively². In lanes *m* are molecular-weight markers of size indicated in kilobases. In lanes *a*–*c*, *D. mauritiana* DNA has been digested with *a*, *Xba*I/*Bam*HI (pPW232.1); *b*, *Xba*I/*Sac*I (pPW232.1); *c*, *Bam*HI/*Sac*I (pPW229.1). B, There are four copies of hsp70-coding sequences in *D. mauritiana* and *D. simulans*. *d*, An *Xba*I/*Bgl*II digest of *D. mauritiana* DNA probed with pPW229.1. *D. simulans* gives identical patterns with all the above digests. C, 'Snapback' hsp70 genes in species related to *D. melanogaster*. Lane *e* contains a *Sac*I digest of *D. mauritiana* DNA (an identical pattern is obtained with *D. simulans*). In lanes *f*–*i*, DNA was denatured, reannealed and digested with S_1 nuclease exactly as described previously¹³, before electrophoresis and transfer hybridization to plasmid pPW229.1. Lane *f* is *D. teisseri*, *g* is *D. yakuba*, *h* is *D. simulans*, and *i* is *D. mauritiana*.

Evolution of the organization of hsp70 genes in *Drosophila*

The members of the *D. melanogaster* subgroup are closely related. A previous study on the polytene chromosome banding patterns has suggested that *D. simulans* and *D. mauritiana* are more closely related to each other than to *D. melanogaster*¹⁴. Two more distantly related species, *Drosophila teisseri* and *Drosophila yakuba*, also have two pairs of hsp70 genes both arranged as inverted repeats (Figure 2C). This indicates that this was the ancestral organization which existed at both 87A7 and 87C1 before the separation of *D. melanogaster* from the other species.

The 87C1 locus in *D. melanogaster* is very different from all the other hsp70 loci (Fig. 1)¹³. It must have arisen through DNA insertion between the two diverging hsp70 genes of the ancestral locus. The intervening region between hsp70 domains at this locus is very large and contains many repeated sequences, including the α and β elements which are also found at the chromocentre and some other sites⁷. The α and β elements are also present at the chromocentre in *D. simulans*² and so may be presumed to have been present before the speciation of *D. simulans* and *D. melanogaster*. As the chromocentral α and β elements of *D. melanogaster* are non-adjacent¹⁶, it would require at least two events to introduce contiguous $\alpha\beta$ elements at 87C1.

Insertions between the two hsp70 genes at 87A7 seem to be common in *D. melanogaster*. The 56H8 clone of Schedl *et al.*¹⁷ derives from this locus and contains a dispersed repetitive sequence between the two hsp70 genes¹⁸. Other changes in the structure of the 87A7 locus in chromosomes derived from natural populations seem to be due to independent events of this type (A.J.L.B., unpublished observations). After heat shock the inserted $\alpha\beta$ elements are transcribed from 87C1 but no other sites to give an abundant polyadenylated RNA^{7,16}. Thus the sequence rearrangements at 87C1 have resulted in activation of previously unexpressed $\alpha\beta$ sequences, although the transcripts do not seem to be essential for viability or fertility^{13,19}. This suggests that DNA rearrangements during evolution may be responsible for more rapid change in gene function than base substitution.

Nucleotide substitution at the hsp70 loci

We can study the evolution of the hsp70 loci using the restriction maps (Fig. 1) to estimate the rate of nucleotide substitution. This is possible because the three maps are independently derived and the two loci were distinguished using locus-specific probes,

649 site differences from the 87A and 87C loci of *Drosophila* species. The 5' and 3'-terminal *Sal*I sites are indicated and the distribution of restriction sites shown. Within a locus z elements are identical unless otherwise indicated. To estimate the probability of parallel change in a restriction site in both members of a pair of z elements (see text), we calculated the proportion of restriction sites conserved between homologous z elements in *D. melanogaster* and each of the other two species⁴². (Independent evidence suggests that *D. simulans* and *D. mauritiana* are more closely related to each other than either is to *D. melanogaster*¹⁴.) The four proportions were pooled to give an overall estimate of the mean number of restriction sites conserved of 0.828. The probability that a given site is different in two homologous z elements is thus $1 - 0.828 = 0.172$, and the probability that the same change occurred independently in a pair of sequences is $0.0297 (= 0.172^2)$. We have found six examples of parallel change in 36 comparisons of restriction site pairs ($P = 0.00062$). kb, Kilobase.

not restriction-site homology. Comparison of hsp70 genes from 87A and 87C in *D. melanogaster* has shown that the non-protein-coding regions have diverged much more than the protein-coding regions^{11,20}. Presumably, the latter are constrained by the need to retain protein function. We have therefore considered the nucleotide substitution of the region coding for hsp70 protein separately from that of the surrounding sequences (Table 1).

We can use the degree of nucleotide divergence to estimate the rate of substitution for the non-protein-coding regions. Carson²¹ has described a correlation in Hawaiian *Drosophila* between estimated divergence time and genetic distance based on frequencies of enzyme variants. The genetic distance between *D. simulans* and *D. melanogaster*²² would suggest a divergence time of about 1×10^6 generations. We estimate the degree of nucleotide substitution in non-coding DNA to be 0.03 per nucleotide (Table 1). This is equivalent to a rate of nucleotide divergence of the order of 3×10^{-8} per nucleotide per generation. Although estimations of divergence time are subject to large errors, we note that this rate is consistent with estimates for primates (approximately 1×10^{-8} per nucleotide per generation) obtained from the measurement of melting points of interspecific hybrid DNA molecules^{23,24}.

Intra-locus gene conversion between z elements

We have remarked previously that z elements from the same locus have similar restriction maps in *D. melanogaster* and suggested that this may imply an intra-locus correction mechanism⁸. We now have supporting data on z elements at six hsp70 loci. There are six examples of parallel change in a particular site in both z elements at the same locus [Fig. 3; *Pst*I (87A *D. melanogaster*); *Sal*I; *Bgl*I (87C *D. melanogaster*); *Pst*I (87C *D. simulans*), and the 3' *Xba*I sites at 87A and 87C in *D. melanogaster* which we discuss in more detail later]. We have estimated the probability of a restriction site changing independently in both members of a pair of z elements to be 0.0297 (see Fig. 3 legend). The probability of making such an observation six times or more in 36 comparisons is 0.00062. Clearly, the loss of restriction sites in both z elements at a locus cannot be independent and we believe that a mechanism is operating which corrects sequence differences that arise between members of a z pair. Three intra-locus restriction site differences occur at the 87C1 locus of *D. mauritiana*. Presumably these have arisen since the last conversion event.

Observations have been made on vertebrate globins which have led to similar conclusions. Duplicated human α -globin

sequences are considerably more similar than expected from the observed species divergence^{25,26}. These sequences are arranged in tandem, and it has been suggested that repeated rounds of unequal crossing-over could explain the observed sequence similarity. This is supported by the discovery of rare variants with three α -globin sequences in tandem²⁵. However, unequal crossing-over cannot act on inverted repeat sequences. We consider a different mechanism to explain the sequence homogeneity we have observed between z elements within hsp 70 loci.

Figure 4 illustrates our proposed mechanism, which is based on previous models, to explain gene conversion during meiosis^{27,28}. Occasional folding back of a chromosome would bring the two z elements in a locus close together in the same orientation. Strand exchange occurring between proximal and distal genes combined with base-mismatch repair could lead to a locus containing a pair of similar z elements. Although Fig. 4 shows symmetric strand displacement, asymmetric exchange will also lead to sequence transfer between proximal and distal genes. The extent of gene conversion will depend on the length of branch migration so that it need not lead to exact similarity between sequence pairs. Note that unequal crossing-over cannot explain such incomplete exchange. A possible consequence of this model is the inversion of the DNA region between the two genes if the two sets of strand breakages occur on opposite strands (Fig. 4C, D). A similar mechanism could also operate between tandem genes except that symmetric exchange would give rise to deletions. Indeed, an intra-chromosomal recombination mechanism in *Drosophila* has been proposed to explain the reversion of certain tandem duplications at the *Bar* and *Beadex* loci in the absence of meiotic recombination and sister-strand exchange²⁹⁻³¹. We note that gene conversion has recently been invoked to explain discontinuities in sequence conservation found between human γ - and α -globin genes³².

Presumably, the likelihood of gene conversion will depend on the distance between the two genes. Thus, one would expect the frequency of intra-locus exchange to be greatly diminished by the insertion of the large $\alpha\beta$ -containing region into the 87C1 locus of *D. melanogaster*. Sequence comparison between gene pairs at 87A7 would allow an estimate of the rate of exchange between two closely spaced hsp70 genes. If the insertion of the $\alpha\beta$ domain into the 87C1 locus causes a dramatic reduction of intra-locus conversion, the rate of nucleotide substitution between proximal and distal hsp70 genes will rise. Determination of the degree of sequence divergence between proximal and distal hsp70 genes at 87C1 in *D. melanogaster* will allow estimation of the time of insertion of the $\alpha\beta$ domain.

Sequence homogeneity between z elements from different loci

In a recent study³³, cloned hsp70 coding sequences derived from *D. melanogaster* were hybridized to the polytene chromosomes of the unrelated species *Drosophila pseudoobscura*. This revealed two linked sites of sequence homology at heat-induced chromosome puffs. These are located on chromosome 2 in *D. pseudoobscura* which corresponds to the chromosome arm (3R) in *D. melanogaster* that contains the hsp70 loci. This suggests that the duplication event which gave rise to two hsp70 loci is very ancient, the *obscura* and *melanogaster* lineages probably diverging in the early Oligocene some 35×10^6 yr ago³⁴. Despite this long separation the z elements of the two loci are very similar.

Comparison of the z elements in the three species studied shows no greater divergence between the two hsp70 loci than that between species at one locus (Fig. 3). In particular, only one restriction site differentiates z elements from the two loci of *D. simulans*. This suggests that a 'correction' mechanism is acting between the two hsp70 loci, despite their being about 500 kilobases apart. Further evidence of such sequence exchange comes from the distribution of *Xba*I sites in the z elements.

All z elements in *D. melanogaster* have an *Xba*I site some 300 bases upstream from the terminal *Sal*I site^{8,11,35}. This site is absent from all copies in *D. simulans* and *D. mauritiana*. Three alternative origins of this distribution can be envisaged: (1) the 3'

*Xba*I site was present in the 'ancestral' z element and was lost from all copies in the lineage which led to *D. simulans* and *D. mauritiana*. (2) The loss of this site is the result of site-specific DNA modification rather than a coincidental change in the primary structure of the DNA of all z elements in *D. simulans* and *D. mauritiana*. (3) The 3' *Xba*I site arose in a z element at one locus in *D. melanogaster*, spread through that locus by an intra-locus conversion mechanism and then to the other hsp70 locus by an inter-locus gene conversion event.

We have data which seem to rule out the first two possibilities. First, none of the slightly more distantly related species, *D. teisseri*, *D. yakuba* or *Drosophila erecta*, has a 3' *Xba*I site in its z elements (A.J.L.B., unpublished observations). According to the first scheme, one or more of these would also be likely to have retained this site, as they are no more closely related to *D. simulans* than to *D. melanogaster*¹⁴.

We have examined the possibility of base modification by analysing the z elements of *D. melanogaster*/*D. simulans* hybrid flies, and find that none of the sequences derived from *D. simulans* has a 3' *Xba*I site and all those from *D. melanogaster* are cut by *Xba*I (codominant inheritance). It is unlikely that the lack of a 3' *Xba*I site in species other than *D. melanogaster* is due to a DNA modification system, although we cannot completely exclude an enzyme active only on previously modified sites.

The third alternative remains: that gene conversion events occur between the two hsp70 loci as well as within a locus. These must be rarer than intra-locus exchanges because we have found only one hsp70 locus with dissimilar hsp70 genes whereas the z elements differ between 87A and 87C1 in all three species studied. The relative rarity of inter-locus exchange reflects the lower likelihood of synapsis between non-adjacent genes. Although we cannot directly determine the frequency of gene conversion between the two hsp70 loci, we can estimate the time of the most recent exchange. The non-protein-coding sequences in z at 87A7 and 87C1 have diverged by 15%^{10,20}. This greatly exceeds our estimate of the degree of nucleotide divergence in noncoding DNA between these species (Table 1), indicating that the last complete conversion between the sequences at 87A7 and 87C1 greatly predated the separation of *D. melanogaster* and *D. simulans*. The conversion of the 3' *Xba*I site in *D. melanogaster* that must have occurred after speciation illustrates that conversion events need only exchange parts of the hsp70 gene. Recently, Scherer and Davis have demonstrated³⁶ gene conversion in yeast between unlinked *his3* genes associated with the yeast transposon, *Ty1*. Evidence for gene conversion events between unlinked suppressor genes in *Saccharomyces pombe* has also been reported³⁷.

The best characterized precedent for gene conversion between distant loci is the switching of mating type in yeast where conversion of the mating-type locus *MAT* by normally silent copies at *HML* and *HMR* has been demonstrated genetically and biochemically^{38,39}. Attempts to detect extra-chromosomal mating-type sequences were unsuccessful³⁸. The alternative model involves conventional recombinational mechanisms and resembles an inter-locus version of our model for intra-locus exchange^{40,41}. We believe that the mechanisms of intra- and inter-locus conversion of hsp70 genes are similar and differ mainly in frequency. Our results clearly indicate that these frequencies are sufficient to be of considerable evolutionary significance.

We thank Drs W. Bender, D. Charlesworth, R. Holliday, C. Langley and J. Williams, and our colleagues in the laboratory for stimulating discussions and criticism of the manuscript. We also thank Drs M. Ashburner, J. P. W. Young and R. A. Voelker for fly stocks, Dr M. Meselson for plasmids pPW229.1 and pPW232.1, and Drs P. Schedl and A. Udvardy for plasmids 56H8 and cHS2S2.

Fig. 4 Mechanism for intrachromosomal gene conversion. Filled boxes indicate coding sequences, transcribed in the direction of the arrow head, and empty ones the complementary sequences. Arrows indicate the sites of DNA strand breaks. The letters a, b and c indicate the orientation of the intergenic region. A, hsp70 gene alignment; B, double-stranded hairpin loop formation; C, strand displacement and exchange with two possible secondary sites of strand breakage; D, the two products. DNA repair will correct the base mismatch at the proximal and distal genes in the same direction in a proportion of these events. Note the inversion of the intervening markers in D(2). The mechanism depicted would operate as readily between sister chromatids as between sequences on the same chromatid. Indeed, a version which converts between paired homologues during meiosis can be envisaged.

Detection of low order p-modes in brightness fluctuations of the Sun

Franz-Ludwig Deubner

Institut für Astronomie und Astrophysik, 8700 Würzburg, FRG

The discovery of radial and non-radial global oscillations of the Sun through various types of detector systems has opened the field of solar seismology. Of particular importance for studies of the deep interior of stars are the detection and analysis of low harmonic order pulsations such as the low order p-modes recently found on the Sun^{1,2} by line shift measurements. These pulsations have now also been detected in the solar brightness fluctuations. Through the reflected light of Uranus and Neptune the Sun was observed as though it were a distant star. The positive results suggest that broad-band photometry has the greatest potential for developing seismometry of main sequence stars.

High overtone pulsations of the Sun, both radial and non-radial (but with low degree l), discovered through line shift observations of the integrated solar disk by means of a potassium resonance spectrometer, have been reported by Claverie *et al.*¹ and confirmed with similar instrumentation operated at the South Pole station by Fossat² and his colleagues (also see ref. 3 for review). The excellent solar results available suggest that this type of measurement should be extended to main sequence stars and other 'nonvariables'. However, because of the lack of photons, the sensitivity of the kind of equipment necessary to select a narrow-band spectral region for line shift analysis is barely sufficient to resolve motions with anticipated amplitudes smaller than a few metres per second, even for the brightest stars⁴. The integrated power in the low order p-mode band has an amplitude of $\sim 2 \text{ m s}^{-1}$. However, decomposition into its individual modes requires a sensitivity better than 20 cm s^{-1} , as in the solar case. For this reason, and also because of the more common availability of good broad-band photometric devices, it is of interest to study the possibility of detecting comparatively short period fluctuations of the integrated intensity related to the p-mode oscillations.

Clearly, one does not hope to see the geometrical effect of a change of the radius by $\delta r/r \approx 1.5 \times 10^{-8}$. It is the enhancement by a factor of 1,000–2,000 of the temperature fluctuation compared with the fractional change of the radius^{3,5} which brings the expected brightness fluctuations into the range of $\delta I/I \geq 2 \times 10^{-5}$ for vertical photospheric motions with the

amplitude (20 cm s^{-1}) and period (5 min) of the p-modes. Compared with common scintillation amplitudes of the order of 10^{-3} mag the expected signals still seem to be much too small to be detected.

For a successful observation of non-radial stellar p-modes it is important to resolve and identify the individual modes, in addition to detecting the signal. To obtain a resolution in frequency sufficient to resolve the solar p-mode spectrum (that is, better than $30 \mu\text{Hz}$), observing sessions of at least 10 h, preferably without interruption, are required. The duration of this observation will then also help to suppress the noise level due to atmospheric scintillation.

A recent search for intensity fluctuations of solar origin in daylight observations of the integral sunlight⁶ was unsuccessful. I have previously obtained⁷ data amenable to similar analysis at the ESO station in Chile, to investigate the presence of fluctuations with periods longer than 10 min in the solar luminosity, as monitored by broad-band dual beam photometry of the brightness of Uranus and Neptune using a 50-cm telescope. Combining observations of 10 successive nights with a mean observing duration of 7.8 produced a r.m.s. noise level of 6×10^{-5} in these data. In the present investigation the spectral analysis was repeated applying a least squares sine wave fitting technique to the complete set of data, to avoid the awkward consequences of the temporal window in a straight Fourier transform with zeroes padded in the data gaps. Power estimates were computed at $(1 \text{ cycle}/14,400) \text{ min}^{-1}$ intervals. The power spectrum is still very noisy and gives only a vague impression of regularly spaced features. Fortunately, asymptotically the p-mode eigenfrequencies are spaced at regular intervals, and the size of this interval is well enough established⁸ to permit a 'superposed frequency' analysis analogous to the superposed epoch technique used to detect non-sinusoidal periodic fluctuations. A superposed frequency analysis applied to a velocity power spectrum, which is analogous to the procedure here, was recently published by Grec *et al.*²

The result of this procedure, averaging 15 frequency segments Δf of $135.42 \mu\text{Hz}$ each, covering the range 2.083–4.167 mHz, is shown in Fig. 1b, accompanied by the 'unfolded' spectral data on the same frequency scale in Fig. 1a. At one position the signal is well above the 3σ level of this mean power distribution, at two more positions the signal exceeds the 2σ level. All three features are accompanied by ghosts at 10 frequency intervals' distance due to the periodic structure of the window function. (The apparent asymmetry of the ghost pattern can be shown by numerical simulation to be due partly to the shape of the window transform and partly to the comparatively high noise level of the data.) The principal frequencies falling next to the mean period of 5 min are 3.301, 3.309 and 3.377 mHz.

Fig. 1 Frequency spectrum of brightness fluctuations of the Sun. Spectral segments of length 135.42 μHz , shown in *a* are averaged to obtain the 'superposed' spectrum in *b*. Three peaks above the 2σ level are believed to represent sets of low order solar p-modes (ghost lines are bracketed). In *a*, the observed spectral frequencies which are believed to represent global p-modes are drawn with heavier lines. The frequency values given refer to the position within each segment marked by the arrows on top. The open dots with error bars in *a* are frequencies observed through line shift observations by Claverie *et al.*⁸. The arrow heads mark three sets of frequencies determined by Fossat (personal communication) from a 5 days continuous observation obtained at the South Pole. The numbered scale below the segmented spectrum indicates the 117 frequency intervals of $(1/14,400) \text{ min}^{-1}$ congruent with the folding interval of 135.42 μHz .

With the improved frequency resolution of this observation, one of the two sets of eigenfrequencies reported by Claverie *et al.*¹ is resolved into doublets at an interval of $\sim 8 \mu\text{Hz}$, similar to Fossat's² result of $10 \mu\text{Hz}$. Identification of these doublets with $l=0$ and $l=2$ modes is consistent with theoretical spectra published by Iben and Mahaffy⁹ and Christensen-Dalsgaard¹⁰. In detail, our observed frequencies agree quite satisfactorily with those obtained by Fossat (personal communication), but are systematically higher by 5–10 μHz than the values given by Claverie *et al.*⁸. To some extent, the accuracy of these latter data may suffer from insufficient spectral resolution. By standard statistical criteria, the significance of the three peaks emerging from the 2σ background of our superposed frequency analysis seems very marginal. We note, however, that of these peaks, two (with $l=1$ and 2) coincide within $\pm 2.25 \mu\text{Hz}$ with the most accurately observed superposed frequencies available. The probability of such a coincidence occurring by chance is 1.7×10^{-2} . Considering the statistical fluctuations of the amplitude estimates of a 10 days' data sample the mode identifications

given in Fig. 1 are consistent with the theoretical result that the mode numbers $l=0, 1$ and 2 are those most favoured by the spatial filter function both of full disk velocity and intensity observations¹¹. Finally, a phase difference of 3.5 yr in the solar activity cycle existing between measurements of intensity⁷ and velocity (E. Fossat, personal communication) should be considered when minor systematic frequency differences among these observations are confirmed.

After subtraction of the noise the observed mean power at the p-mode frequencies corresponds to a r.m.s. amplitude of $4\text{--}5 \times 10^{-5}$, in good agreement with our expectation. The improved signal-to-noise ratio obtained with stellar objects brighter than Uranus and Neptune, and with larger telescopes should facilitate the analysis by making the periodic structure stand out against the straight unfolded spectrum.

I thank G. Isaak and E. Fossat for unpublished results, and for exciting discussions.

Solar neutrinos and turbulent diffusion

E. Schatzman

Observatoire de Nice, BP 252, Nice Cedex 06007, France

A. Maeder

Observatoire de Genève, 1290 Sauverny, Switzerland

Stellar rotation generates instabilities¹ which have not been taken into account in classical computations of stellar evolution. In particular, these instabilities may produce turbulent diffusion with important consequences over long time scales. Thus it has been shown^{2,3} that the loss of angular momentum which occurs in the external stellar layers due to stellar wind and magnetic braking⁴ leads to a redistribution of angular momentum. We show here that there are observational and theoretical reasons to suspect that a slow diffusion process due to a mild turbulence is operating in stellar interiors. Turbulent diffusion may have important consequences for the solar neutrinos problem and the (³He/⁴He) ratio at the solar surface.

The necessary and sufficient condition for the generation of turbulence has been often discussed. The presence of shear is a necessary but not sufficient condition; the Richardson criterion⁵ has also to be satisfied. But, when account^{6–8} is taken of the heat exchange between the moving fluid and the surrounding medium the Richardson criterion has to be replaced by the less stringent Townsend criterion or flux Richardson criterion. Eliassen and Kleinschmidt⁹ used the Townsend criterion to describe the maintenance of turbulence which is the same as that used by Zahn⁸. These conditions naturally differ from those of Layzer¹⁰, who has assumed that no heat exchange takes place during the motion of the fluid, a more stringent requirement.

The Rayleigh condition, states that, as long as $\delta\Omega/\delta z = 0$, the fluid is stable provided $\delta(\Omega\varpi^2)/\delta\varpi < 0$, Ω being the angular velocity and ϖ the distance to the axis. This last condition is violated if the star, like the Sun, is losing angular momentum. But as soon as $\delta\Omega/\delta z \neq 0$ the rotational motion is dynamically unstable¹¹. It has been shown that there is no meridional circulation which can be stable everywhere in a star^{12,13}.

where that the absence of turbulence in the radiatively stable region of the Sun would be remarkable¹⁴. We assume that instabilities associated with the shear flows in differentially rotating stars generate a mild turbulence, the effects of which may be treated¹⁵ as a diffusion process in stellar evolution.

Several astrophysical observations seem to support the mechanism of turbulent diffusion. Schatzman¹⁶ suggested that turbulence could inhibit gravitational (and radiative) sorting of the elements, and Baglin¹⁷ showed that meridional circulation for fast-rotating stars can induce a sufficiently high level of shear flow turbulence to avoid the sorting of elements. The Li deficiency in giants of spectral types F and G has been measured by Alschuler¹⁸. Assuming that these giants belong to the first ascending branch, and that their mass can be derived from Iben's¹⁹ evolutionary tracks, the Li deficiency can be explained by Li burning during the main sequence phase: Li is carried by turbulent diffusion from the outer layers of the star towards the region where it is nuclearly processed and destroyed. For masses $M \leq 1.6 M_{\odot}$, the empirical estimates of this rate of Li destruction on the main sequence²⁰ essentially agree with the theoretical values based on the turbulent diffusion model.

The ^{13}C excess in giants of the first ascending branch²¹, can be accounted for by turbulent diffusion²² outwards from the region where ^{12}C is nuclearly processed and partly transformed into ^{13}C .

Note that the equations for a slow diffusion process in stellar evolution are quite different from those for convective mixing. In particular, homogenization in finite volumes²³ does not properly mimic a slow diffusion process. This can be explained by a simple physical argument. The complete mixing over a fraction q_m of the solar mass²³⁻²⁶ generates a step function of the chemical composition, with a jump in the chemical composition at the mass fraction q_m . For solar models, with the constraint that the luminosity is $L = L_{\odot}$ for $t = 4,650$ Myr, we have $L \sim X_{1\text{en}}^2 T_c^4$, where $X_{1\text{en}}$ is some convenient average value of the hydrogen concentration X_1 . This means that $T_c \sim X_{1\text{en}}^{-1/2}$. With the power law approximation²⁷ $\phi_{\nu} \sim T_c^{20} X_4 (1 + X_1)^{-1}$, the reduction in the neutrino flux is given by

$$\frac{(\phi_{\nu})_{\text{mixed}}}{\phi_{\nu}} \approx \left(\frac{X_{1c}}{X_{1\text{en}}} \right)^{-10} \frac{(X_4)_{\text{mixed}}}{X_4} \frac{(1 + X_1)}{(1 + X_1)_{\text{mixed}}}$$

Fig. 1 Curves X_H give the hydrogen concentration as a function of the mass fraction. Turbulent diffusion brings hydrogen in the core of the Sun. Curves X_3 gives the ^3He concentration as a function of the mass fraction. Turbulent diffusion smoothes the ^3He peaks, with ^3He appearing at the surface and the concentration of ^3He increasing by an appreciable amount in the centre. The maximum X_3 corresponds to 2.8×10^{-3} . The increase of the concentration of the nuclear fuel in the centre is balanced by a decrease of the central temperature which produces a drastic reduction in the neutrino flux. Meanwhile, ^3He appears at the surface of the Sun.

The ratio $(X_{1c}/X_{1\text{en}})$ is always smaller for fully mixed models to $M = q_m M_{\odot}$ than for models where diffusion mixing has taken place. This is because the step function of the chemical composition is not a true description of the distribution of the chemical composition due to the diffusion process.

Schatzman¹⁵ and Genova and Schatzman²² demonstrated that a turbulent diffusion coefficient $D = Re^* \nu$, can be used where ν is the microscopic viscosity (molecular plus radiative) and Re^* is a critical Reynolds number of the order of 100. The changes of compositions in stellar models due to both the nuclear reactions and the turbulent transport may be expressed as:

$$\rho \frac{\partial X_1}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} r^2 \rho D \frac{\partial X_1}{\partial r} + \rho A_1 m_H (-3R_{11} + 2R_{33} - R_{34})$$

$$\rho \frac{\partial X_3}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} r^2 \rho D \frac{\partial X_3}{\partial r} + \rho A_3 m_H (R_{11} - 2R_{33} - R_{34})$$

$$\rho \frac{\partial X_4}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} r^2 \rho D \frac{\partial X_4}{\partial r} + \rho A_4 m_H (R_{33} + R_{34})$$

X_1 , X_3 and X_4 are functions of r and t and represent the abundances, expressed in mass fraction, of ^1H , ^3He and ^4He respectively. ρ is the density and the R_{ij} terms are the nuclear reaction rates²⁸ for the species ij . An efficient matrix scheme for the diffusion equations²⁹ has been incorporated into our stellar evolution code.

Models with $Re^* = 200$, 100 and 0 (standard case) for an initial composition $X_1 = 0.73$, $X_4 = 0.25$ and $Z = 0.02$ have been computed. We note the following main results. As shown in Fig. 1, which gives the distribution of X_1 and X_3 in the Sun at $t = 4,600$ Myr, there is much more central hydrogen in the present Sun when diffusion is included. While the central X_1 is only 0.359 in the standard case, it is 0.569 with $Re^* = 100$. This excess of central X_1 evidently results¹⁵ from the inward transport due to a positive abundance gradient. Outside the central regions, the differences are smaller and of opposite sign. Overall, turbulent diffusion makes the X_1 distribution much flatter.

The internal distribution of ^3He shows a peaked distribution in the standard model (see Fig. 1). With turbulent diffusion, with $Re^* = 100$ and 200, the distribution of ^3He below $M_r/M = 0.4$ is still mainly determined by the rapid equilibrium between creation and destruction as in the standard case. Above $M_r/M = 0.4$ ($T < 8.3 \times 10^6$ K), the transport by turbulent diffusion tends to unify the ^3He distribution³⁰: the peak is reduced and ^3He is spread throughout the star. Figure 1 shows that the surface ratio $^3\text{He}/^4\text{He}$ is considerably increased by turbulent diffusion. An acceptable observational value of this ratio^{31,32} is $^3\text{He}/^4\text{He} \approx 4 \times 10^{-4}$. This value is $\sim 2-4$ times larger³³ than that of the protosolar material and implies a surface enrichment in ^3He during solar evolution. This result supports the occurrence of turbulent diffusion with a value of $Re^* \approx 60$.

The decrease of the mean molecular weight in the interior due to diffusion leads to a decrease of the central temperature and density and, in models with turbulent diffusion, the central concentration of ^3He is increased. Some characteristics of the models at $t = 4,600$ Myr are given in Table 1. We see that the neutrinos flux is smaller by a factor of 8.1 for $Re^* = 200$, 4.9 for $Re^* = 100$ and 2.6 for $Re^* = 50$ relative to the flux obtained in the standard case $Re^* = 0$.

The constraint on the solar luminosity usually fixes the helium content in the initial model; a change of X_4 by -0.01 reduces the luminosity by $\log L = -0.028$. Table 1 shows that diffusion models may fulfill the requirement on solar luminosity with a helium content differing only by 0.01–0.02 from that of the standard case.

Estimates have been made of the possibility of choosing a Z (heavy elements), X_4 (Helium) and Re^* to fulfill the three main requirements: the value of the solar luminosity, the ^3He concentration at the surface and the solar neutrino flux. As a whole, models with turbulent diffusion with Re^* in the range

Table 1 Properties of the standard model of the Sun and of the models with turbulent diffusion mixing at $t = 4,600$ Myr

Re^*	$\log T_c$	$(X_1)_c$	$(X_3)_c$	N_ν (SNU)	$(X_3/X_4)_s$	$\log L/L_\odot$
0	7.1944	0.3585	$8 \cdot E-6$	11.66	—	0.048
100	7.1681	0.5685	$2.1 \cdot E-5$	2.38	$1.57 \cdot E-3$	0.009
200	7.1601	0.6164	$2.6 \cdot E-5$	1.43	$3.38 \cdot E-3$	0.003

$X = 0.73$, $Y = 0.25$, $Z = 0.02$.

$(X_1)_c$ is the hydrogen concentration in the centre; $(X_3)_c$ is the ^3He concentration in the centre; $(X_3/X_4)_s$ is the surface concentration ratio of ^3He and ^4He at the surface.

50–100 seemed to fulfill the main solar constraints for a standard composition.

Our solution overcomes the difficulties of the low X_4 and low Z solar models³⁴. However, recent observations of the solar oscillations³⁵ have led Christensen-Dalsgaard and Gough³⁶ to describe solar models which agree with standard models. The difficulty³⁷ due to migration of heavy elements through a shallow convective zone can be avoided. The same model explains the depletion of lithium at the surface of the Sun.

From dimensional arguments alone we can see that the depletion of lithium would be of the order of $\exp[-(t_0/\tau_{\text{Li}})]$ and the depletion of Be would be of the order of $\exp[-(t_0/\tau_{\text{Be}})]$. τ_{Li} and τ_{Be} are of the order of $(\Delta r)_{\text{Li}}^2 D_{\text{turb}}^{-1}$ and $(\Delta r)_{\text{Be}}^2 D_{\text{turb}}^{-1}$ respectively, where $(\Delta r)_{\text{Li}}$ and $(\Delta r)_{\text{Be}}$ are the respective distances from the bottom of the hydrogen convective zone to the Li burning and Be burning regions. From the values of the Li depletion factor ($\approx 4.8 \times 10^2$) and of the Be depletion factor (≈ 2), and knowing the temperatures of the Li and Be burning regions ($T_{\text{Li}} \approx 2.4 \times 10^6$ K; $T_{\text{Be}} \approx 3.5 \times 10^6$ K), we can derive both where the hydrogen convective zone ends and the value of the turbulent diffusion coefficient (in fact, we do not obtain the bottom limit of the convective zone, but the point at which the penetrative convection T_{PCE} becomes inefficient):

$$\begin{aligned} T_{\text{PCE}} &= 2.19 \times 10^6 \text{ K} & R - r_{\text{PCE}} &= 2.06 \times 10^5 \text{ km} \\ T_{\text{Li}} &= 2.4 \times 10^6 \text{ K} & r_{\text{PCE}} - r_{\text{Li}} &= 0.2 \times 10^5 \text{ km} \\ T_{\text{Be}} &= 3.5 \times 10^6 \text{ K} & r_{\text{PCE}} - r_{\text{Be}} &= 1.24 \times 10^5 \text{ km} \end{aligned}$$

These values are compatible with those of Christensen-Dalsgaard and Gough³⁶. From the value of D_{turb} we obtain $Re^* \approx 85$ which is compatible with the values derived from the other solar constraints.

Meridional circulation³⁸ does not yield the same result. Meridional circulation drives the matter down from the bottom of the hydrogen convective zone to where the Li and Be are burning, and will not differentiate between Li and Be: the characteristic time of depletion being determined by the velocity of the circulation would be the same for both elements. Unless there was a very peculiar pattern of the meridional circulation, we can consider that this is a very strong argument in favour of turbulent diffusion and against meridional circulation²⁸.

We now comment on the role of turbulent diffusion in relation to the neutrino mass³⁹. Proposed values of the neutrino mass favour the suggestion^{40–42} that the neutrino oscillates between the Sun and the Earth. However, the non-zero mass of the neutrino does not necessarily imply an oscillation⁴³. It is therefore worth considering the consequence of change in the stellar models by introducing a simple physical effect and studying its implication for the Sun and the stars. It is difficult⁴⁴ to resolve the difference between predictions based on the solar models and observations by invoking neutrino oscillations only, if there are only three kinds of neutrinos coupled to each other. The probability of finding an electron neutrino after a time t is estimated by Bahcall and Frautschi⁴⁵ to be 0.5 and by Barger *et al.*⁴⁶ to be 0.62. With the latter value, this decreases for a standard model⁴⁴ the observable neutrino flux to 4.65 SNU, far above the observed flux.

How will the Sun evolve within the above framework? This question is particularly important in relation to stellar observations. Clearly, if turbulent diffusion were always maintained, a $1 M_\odot$ star would never become a red giant as the evolutionary time scale for such a star is larger than the diffusion time scale. The star would evolve towards the region of blue stragglers. To obtain an evolution towards the giant branch, turbulent diffusion has to be stopped. The progressively increasing μ -gradient during evolution probably⁸ has a stabilizing effect on the shear flow and consequently the turbulent diffusion would cease when the μ -gradient became large enough.

This suggests the existence of two groups of stars: (1) those with a very low differential rotation, which pursue a standard evolution; (2) those with a high degree of differential rotation, which evolve towards the blue-straggler region. There might also exist a wide range of intermediate cases for which the evolution towards the red-giant branch is only delayed and not stopped completely. This possibility seems very likely because cluster observations indicate⁴⁷ that the width of the main-sequence band is considerably larger than that given by standard models.

Although the evolution of the Sun is not very advanced, previous considerations suggest that this evolution would not necessarily follow route (1) above. In fact, we cannot yet estimate properly the period of rotation of the solar core. The minimum requirement for maintaining the turbulence is that the flux Richardson criterion is satisfied. This somehow gives the minimum angular velocity which might be present inside the Sun. Following Zahn⁸ this can be written

$$\varpi \frac{d\Omega}{d\varpi} \geq (\sigma Re_{\text{crit}}) \left(\frac{g}{H_p} \right) (\nabla_{\text{ad}} - \nabla_{\text{rad}})$$

where $\sigma = (\nu/\lambda_{\text{th}})$, ratio of viscosity to the thermal diffusivity is the Prandtl number, Re_{crit} the critical Reynolds number, H_p the pressure scale height and $\nabla = (d \log T / d \log P)$. This leads to a minimum value of Ω in the solar core, corresponding to a period of 2–3 days, in agreement with a vanishingly small oblateness. The turbulent diffusion coefficient for angular momentum therefore does not have a simple relationship with the turbulent diffusion coefficient for chemical species. Some feedback must exist, between loss of angular momentum, transport of angular momentum and turbulence which presumably stabilizes the critical Reynolds number Re^* around 100.

Solvent inclusion and disorder effects on an isostructural series of organic conductors

G. J. Ashwell

Department of Chemistry, Sheffield City Polytechnic, Pond Street, Sheffield S1 1WB, UK.

Interest in quasi-one-dimensional organic conductors has been renewed by the discovery¹ of superconductivity in (tetramethyltetraselenafulvalene)₂PF₆, (TMTSF)₂PF₆. At ambient pressure (TMTSF)₂PF₆ undergoes a Peierls distortion at 18 K (ref. 2) whereas under modest pressure the properties remain metallic with the onset of superconductivity at 0.9 K (ref. 1). There is now an incentive to synthesize other organic metals in which the Peierls distortion is suppressed in the hope that these may also superconduct under pressure. So far (DEPE)(TCNQ)₄(H₂O)_x is the only example^{3,4} to show a monotonic increase in conductivity, characteristic of a metal, on cooling at ambient pressure to below 30 mK. This metallic behaviour has, however, been disputed⁵. I verify here the unique temperature dependence of conductivity of (DEPE)(TCNQ)₄(H₂O)_x and report the electrical and structural properties of the isostructural congeners (DMPP)(TCNQ)₄(H₂O)_x and (DRPA)(TCNQ)₄(H₂O)_x where R = M (methyl) and E (ethyl) (see Table 1 for full names).

Needle-shaped crystals, 2 × 0.1 × 0.01 mm, were prepared by a method reported previously⁴ for bipyridinium-TCNQ salts. The crystals were fibrous and frequently bowed indicating a weak coupling between chains. The stoichiometries were

Fig. 1 Variation of the normalized conductivity with temperature of two crystals of (DEPE)(TCNQ)₄(H₂O)_x, one semiconducting (○) and the other metallic (●).

Fig. 2 Variation of the conductivity with temperature of (DEPA)(TCNQ)₄(H₂O)_x.

determined by elemental (C, H, N and O), spectral and thermogravimetric techniques (Table 1). The space group and unit cell parameters were obtained from oscillation and Weissenberg photographs using CuKα radiation (Table 2). Oscillation photographs about *b* showed strong subcell layer lines with *d*-spacings of 3.84–3.85 Å and weak layer lines with *d*-spacings of 17.4 Å in (DEPE)(TCNQ)₄(H₂O)_x, 17.1 Å in (DMPP)(TCNQ)₄(H₂O)_x and 7.68 Å in (DMPA)(TCNQ)₄(H₂O)_x. When the crystals were annealed in vacuum at ~370 K the weak layer lines could no longer be observed. In these conditions dehydration occurs with a contraction of the unit cell. The unit subcell parameters of (DMPP)(TCNQ)₄(H₂O)_x, refined on a Hilger and Watts four-circle diffractometer, were *a* = 12.93(2), *b* = 3.85(1), *c* = 27.50(2) Å, β = 108.1(2)°, *U* = 1,301 Å³ before annealing and *a* = 12.84(1), *b* = 3.84(1), *c* = 27.31(6) Å, β = 106.6(3)°, *U* = 1,290 Å³ after. In these quasi-one-dimensional conductors the weak layer lines are attributed to the H₂O lattice, commensurate in (DMPA)(TCNQ)₄(H₂O)_x and incommensurate in (DEPE)(TCNQ)₄(H₂O)_x and (DMPP)(TCNQ)₄(H₂O)_x. Variations in the intensities of the weak layer lines may indicate incomplete hydration and therefore a random occupancy of the available sites within a well defined H₂O lattice.

In (DEPE)(TCNQ)₄(H₂O)_x, (DMPP)(TCNQ)₄(H₂O)_x and (DMPA)(TCNQ)₄(H₂O)_x the cation lattice is inherently disordered which is characteristic of all highly conducting TCNQ salts with stoichiometries other than 1:1. The TCNQs stack plane-to-plane within homologous columns^{6,7} parallel to *b* with (1) a uniform mean interplanar spacing of 3.2 Å and (2) an exocyclic double bond to quinonoid ring overlap of adjacent molecules, with the longitudinal molecular staggering in a consistent direction throughout the stack. At ambient temperature the disorder inhibits a periodic coupling of the anion and cation chains and so suppresses the onset of a three-dimensional transition to a less conducting phase. At ~40 K the crystals undergo conductor-to-insulator transitions (Figs 1, 3) which are attributed to distortions of the quasi-one-dimensional TCNQ lattice. In these salts it is improbable that interactions between the conduction band electrons and the H₂O lattice, incommensurate in (DEPE)(TCNQ)₄(H₂O)_x and (DMPP)(TCNQ)₄(H₂O)_x, are sufficient to cause the Peierls distortions at

	Found	71.01	3.23	24.80	1.36	2.1	

Values calculated by assuming: * $x = 0.88$; † $x = 0.90$ and ‡ $x = 1.0$. The non-stoichiometry is suggested by X-ray analysis; weak layer lines with d -spacings of $b/0.22$ in (DEPE)(TCNQ)₄(H₂O)_x and $b/0.225$ in (DMPP)(TCNQ)₄(H₂O)_x are attributed to an incommensurate H₂O lattice.

(DEPE)(TCNQ)₄(H₂O)_x = [1,2-bis(1-ethyl-4-pyridinium)ethylene]²⁺(7,7,8,8-tetracyanoquinodimethanide)₄²⁻(H₂O)_x. (DMPP)(TCNQ)₄(H₂O)_x = [1,3-bis(1-methyl-4-pyridinium)propane]²⁺(7,7,8,8-tetracyanoquinodimethanide)₄²⁻(H₂O)_x. (DMPA)(TCNQ)₄(H₂O)_x = [1,2-bis(1-methyl-4-pyridinium)ethane]²⁺(7,7,8,8-tetracyanoquinodimethanide)₄²⁻(H₂O)_x.

~40 K. If they were we should expect the transition in (DMPA)(TCNQ)₄(H₂O)_x to occur at a higher temperature, as the H₂O lattice is commensurate in this salt. Instead I suggest that the distortions arise, in part, from an ordering of the cation lattice on cooling.

The conductor-to-insulator transitions at 40 K have been suppressed, in a few instances only, by annealing the hydrated crystals in vacuum (10⁻⁴ torr). The conductivities increased on dehydration. For (DEPE)(TCNQ)₄(H₂O)_x, shown in Fig. 1, the conductivity decayed on thermal recycling but, nevertheless, remained metallic. For (DEPA)(TCNQ)₄(H₂O)_x, shown in Fig. 2, the conductivity was reproducible for two cooling cycles (300–10 K) and increased monotonically on cooling to below 10 K. In this low temperature region the properties depend on the degree of disorder which, in the limit, can obscure the Peierls transition by, for example, introducing a substantial density of states into the band gap as exemplified by recent work on (dimethyldiphenylphosphonium)⁺(TCNQ)₂⁻ (ref. 8). The experimental data reflect an increase in the disorder on dehydration and a decrease on thermal recycling.

The electrical properties of (DEPE)(TCNQ)₄(H₂O)_x, (DMPP)(TCNQ)₄(H₂O)_x, (DMPA)(TCNQ)₄(H₂O)_x and (DEPA)(TCNQ)₄(H₂O)_x depend on the outgassing procedure.

**Fig. 3** Variation of the normalized conductivity with temperature of (DMPA)(TCNQ)₄(H₂O)_x.**Fig. 4** Variation of the thermoelectric power with temperature of two compacted pellets of (DEPE)(TCNQ)₄(H₂O)_x, one hydrated (○) and the other dehydrated (●).

Crystals annealed in vacuum at 300–400 K have variable properties which may be attributed to the onset of decomposition, increased disorder and to loss of solvent from the lattice. Five crystals have shown metallic behaviour with $\sigma_{300K} = 100$ –500 S cm⁻¹ along b . Most were semiconducting with $\sigma_{300K} = 50$ S cm⁻¹. The metallic crystals are believed to be more disordered and less hydrated than the semiconducting crystals. For a correlated semiconductor the thermoelectric power, S , is given⁹ by

$$S = -k/e \ln[2(1-\rho)/\rho] \mu V K^{-1}$$

where ρ is the ratio of carriers to available TCNQ sites. Assuming that charge transfer is commensurate with the chemical formulae presented for the isostructural series, $\rho = 0.5$ and $S = -59.8 \mu V K^{-1}$. For (DEPE)(TCNQ)₄(H₂O)_x this theoretical value is consistent with the experimental data at saturation for the hydrated sample only (Fig. 4). The semiconducting behaviour probably arises from a pinning of the charge density waves by the H₂O 'impurities'. When the pinning is destroyed, by dehydration, the conductivity is enhanced and may become metallic. Thus in the dehydrated sample the thermoelectric

Table 2 Unit subcell parameters of the strong layer lines and d -spacings of the weak layer lines of the isostructural series of conducting TCNQ salts

The weak layer lines are attributed to the H₂O lattice.

e.m.f. is significantly lower and the properties are no longer consistent with those of a correlated semiconductor. On dehydration there is no significant change in the TCNQ stacking characteristics.

All four salts have crystallographically ordered anhydrous modifications. In these the TCNQs are stacked plane-to-plane in stoichiometric groups of four, in a direction parallel to the length of the cation, with no direct overlap between adjacent tetrads. This periodic distortion arises from a periodic coupling of the anion and cation chains. The conductivities are significantly lower with $\sigma_{300K} \sim 0.002 \text{ S cm}^{-1}$ along b , the direction of stacking. Conversely in the crystallographically disordered modifications the periodic interchain coupling is destroyed by cation disorder and homologous columns of TCNQs occur. In both types of modification the electrical properties are consistent with those of related complexes in which the TCNQ stacking characteristics are similar.

I thank Dr S. C. Wallwork for the refined subcell parameters of $(\text{DMPP})(\text{TCNQ})_4(\text{H}_2\text{O})_x$ and Dr G. Owen for helpful discussions. I also thank G. H. Cross for assistance with the conductivity measurements and the Chemical Society Research Fund and the SRC for support.

High abundances of long-chain normal alkanolic acids in Antarctic soil

Genki Matsumoto*, Tetsuya Torii†
& Takahisa Hanya*

† Chiba Institute of Technology, Tsudanuma, Narashino, Chiba Prefecture 275, Japan

Studies of geochemical samples have shown that fatty acids are widely distributed in sediments ranging in geological age from Recent to Precambrian¹⁻⁹. Most *n*-alkanoic acids found in soils and Recent sediments show similarities in their distributions, such as a marked predominance of even-carbon numbered acids and a bimodal distribution with two maxima in carbon chain length of C_{14} to C_{18} and C_{24} to C_{28} (refs 1, 2, 4-7). Long-chain *n*-alkanoic acids ($\geq \text{C}_{20}$) predominate in the waxes of vascular plants^{10,11}, whereas short-chain *n*-alkanoic acids ($< \text{C}_{20}$) occur in the lipids of all living organisms. Long-chain *n*-alkanoic acids found in soils and Recent sediments are thus believed to arise from vascular plants¹²⁻¹⁴. In Antarctica, vascular plants are only found in the Antarctic Peninsula¹⁵. Organic constituents on this continent are thus expected to be considerably different from those in the temperate and tropical zones. We report here the presence of very long-chain *n*-alkanoic acids extending to C_{40} , having a small even-carbon predominance, and comprising a large proportion of the fatty acids in Antarctic soils. They apparently originate in the Beacon Sandstone.

During the 1967-77 austral summer, soil samples were collected from the dry valleys of Victoria Land in Antarctica (Fig. 1) with a small stainless-steel scoop, wrapped in Teflon sheet and stored at temperatures below 0°C until analysis. The

procedures for fatty acid analysis have been described in detail elsewhere¹⁶. Briefly, wet samples ($\sim 50 \text{ g}$) were extracted with ethyl acetate after saponification with 0.5 M potassium hydroxide/methanol solution. Each extract was chromatographed on a silica gel column ($160 \times 4\text{-mm}$ i.d., 100 mesh, 5% water). After elution with two column volumes of hexane, the eluate (fatty acid fraction) obtained with three column volumes of benzene/ethyl acetate (95/5) was methylated with 15% boron trifluoride/methanol solution (3 ml, 80°C , 2 h). The structures of the methyl esters of fatty acids were determined using a combined Shimadzu LKB 9000 gas chromatograph-mass spectrometer in conditions given in Fig. 2.

Fatty acids were identified by comparing their retention times and mass spectra with those of authentic compounds and homologues. Quantitative acid data were obtained by measuring the peak area on the mass fragmentogram or gas chromatogram (total ion current). A blank test to check contamination throughout the experiments indicated possible contaminants (Fig. 2), but they were present in such low amounts that they did not affect the analytical results for long-chain *n*-alkanoic acids. Based on four replicate addition experiments using authentic compounds, the percentage recoveries of *n*-alkanoic acids, C_{14} , C_{16} , C_{18} , C_{20} and C_{22} , were 88 (s.d. 4.0), 91 (8.0), 87 (3.5), 88 (3.7) and 107 (13), respectively.

Fig. 1 Sampling locations in the dry valleys of Victoria Land in Antarctica. 1, Vanda-1; 2, Vanda-2; 3, Bonney, east lobe; 4, Bonney, west lobe-1; 5, Bonney, west lobe-2; 6, Joyce.

The analytical results from six soil samples are summarized in Table 1. The total acid content of the soils is fairly low, ranging from 0.16 to $3.7 \mu\text{g per g}$ dry soil, presumably reflecting the low organic carbon contents ($0.14\text{--}0.71 \text{ mg C per g}$)¹⁶. *n*-Alkanoic acids ranging from C_8 to C_{40} were found with a bimodal distribution maximizing at C_{16} and C_{28} , together with branched (iso and ante-iso) and unsaturated acids (Fig. 2). As far as we know, this is the first report of the occurrence of such very long-chain *n*-alkanoic acids ($> \text{C}_{38}$) in soils and modern and ancient sediments.

Surprisingly, long-chain *n*-alkanoic acids comprised most of the fatty acids, ranging from 30.2 to 81.9% with an average of $53.8 \pm 18.7\%$ at 90% confidence limits, with a small even-carbon predominance. Thus the ratios of long- to short-chain *n*-alkanoic acids are very high (2.7 ± 1.7) and comparable with the value estimated for a forest soil (2.3)¹¹. The carbon preference indices, CPI_{AL} , CPI_{AH} and CPI_{AT} , calculated over the ranges $\text{C}_{13}\text{--}\text{C}_{19}$, $\text{C}_{19}\text{--}\text{C}_{33}$ and $\text{C}_{13}\text{--}\text{C}_{33}$ according to Kvenvolden¹⁴, ranged from 4.5 to 13, 1.4 to 3.6 and 1.7 to 5.7, respectively. In general, these values are lower than those in common biological materials. In particular, the CPI_{AH} and CPI_{AT} values of the three Bonney samples are extremely low, and are thought to be the smallest values ever reported for soils, although CPI_{A} values close to unity have been found in some

Table 1 Fatty acids found in soils collected from the dry valleys of Victoria Land in Antarctica

Locality	Nature of soil	Range	Maximum at carbon number*	Concentration (μg per g)	Composition (%)				Ratio long/short	CPI _{AL}	CPI _{AH}	CPI _{AT}

Carbon preference indices, CPI_{AL}, CPI_{AH} and CPI_{AT}, values were calculated from the carbon chain lengths of C₁₃-C₁₉, C₁₉-C₃₃ and C₁₃-C₃₃, respectively. Short, short-chain *n*-alkanoic acids (C₁₃-C₁₉). Long, long-chain *n*-alkanoic acids ($\geq$ C₂₀). Branched, branched acids (iso and ante-iso, C₁₃-C₁₇). Unsaturated, unsaturated acids (C₁₆ and C₁₈). OY, olive yellow; DYB, dull yellowish brown; sand, coarse and fine sands; GO, greyish olive. YB, yellowish brown.

* The major distribution maximum is underlined.

sedimentary rocks and shales^{1,2,4}. However, we found no long-chain *n*-alkanoic acids with small CPI_A values, which make up a high proportion of the fatty acids in lake waters, sediments and epibenthic algae, that is, blue-green algae (mostly *Oscillatoria* spp., *Phormidium* spp. and *Calothrix* spp.), in samples collected from Lakes Vanda, Bonney and Joyce^{16,17}.

Little is known about the occurrence of long-chain *n*-alkanoic acids other than in the waxes of vascular plants^{10,11} and bees waxes^{18,19}. There are no vascular plants and bees in the areas studied and these long-chain *n*-alkanoic acids are not due to contamination during analysis. There seem to be at least three possible sources of these unusual *n*-alkanoic acids.

(1) An input of aeolian dust, because air-borne pollutants such as dichlorodiphenyl-trichloroethane are found in Antarctic snow²⁰. Some aeolian dusts collected at sea near land areas contain long-chain *n*-alkanoic acids in large relative abundances, but their CPI_A values (6.1-22.0) are considerably higher than ours²¹. Furthermore, the fatty acid ($\geq$ C₁₀)/*n*-alkane ($\geq$ C₁₅) ratios of the aeolian dusts (0.088-0.50)²¹ are much lower than those of the Antarctic soils (31-110, ref. 16; Matsumoto *et al.*, unpublished results). Thus aeolian dust is not the main source of our fatty acids.

(2) Microbial oxidation of *n*-alkanes, because many kinds of microorganism including bacteria and fungi are found in soils in the dry valley areas²². Although *n*-alkanes ranging from C₁₅ to C₃₇, with the most dominant peak at C₂₃ or C₂₇, were found at very low total amounts, between 0.0045 and 0.055 $\mu\text{g per g}$ dry

soil (ref. 16; Matsumoto *et al.*, unpublished results), they could not give our fatty acid profile after microbial oxidation (Fig. 2, Table 2). Thus *n*-alkanes are also an unlikely source.

(3) Glacial erosion of sedimentary rocks containing organic materials may have contributed long-chain *n*-alkanoic acids or precursors, as long-chain *n*-alkanoic acids having small CPI_A values, and high long/short chain ratios have been found in sedimentary rocks and shales of Palaeozoic to Cenozoic age from the US^{1,2,4}. In our case, the dry valley areas are mainly composed of sedimentary, metamorphic and igneous rocks of Precambrian to Cretaceous age. It is well known that the Beacon Sandstone, composed of sandstone, siltstone, conglomerate and carbonaceous beds, and including various fossils such as coals and silicified woods, is widely distributed in the dry valley areas²³. Much of the sedimentary organic carbon in the Ross Sea is reported to be derived from the rocks being eroded by glaciers on the Antarctic continent²⁴. It is therefore likely that the long-chain *n*-alkanoic acids found in Antarctic soils come from the Beacon Sandstone. On the other hand, the short-chain acids, which are similar to those of common biological materials, can be mainly attributed to recent biological sources. Further samples of Antarctic sedimentary rocks including fossils will be collected for the analysis of organic constituents.

We thank Mr Y. Tanaka, Chiba Institute of Technology, the Antarctic Division, DSIR, New Zealand, the US NSF and the National Institute of Polar Research, Japan, for their support in collecting samples.

Fig. 2 Mass fragmentogram (m/e 74) of the fatty acid fraction obtained from soil sample collected from Victoria Land in Antarctica (Bonney, west lobe-1). Conditions: silanized glass column (200 cm $\times$ 3 mm i.d.) packed with 1% silicone OV-1 on 80-100-mesh Chromosorb W AW DMCS; temperature, injector 300 °C, column programmed from 100 to 290 °C at 6 °C min⁻¹, molecular separator 300 °C, ion source 330 °C; carrier gas, helium at 30 ml min⁻¹; acceleration voltage, 3.5 kV; electron energy, 20 eV; multiplier gain, 3. Arabic figures at the peaks indicate the carbon chain length of fatty acids. 13b, 14b, 15b and 17b are branched (iso + ante-iso) C₁₃, C₁₄, C₁₅ and C₁₇ acids, respectively. 16u and 18u are unsaturated C₁₆ and C₁₈ acids, respectively.

α -Particle radioactivity of hot particles from the Esk estuary

E. I. Hamilton

Institute for Marine Environmental Research, Prospect Place,
The Hoe, Plymouth PL1 3DH, UK

Transuranium radionuclides (Pu, Am and Cm) present in effluents discharged into the north-east Irish Sea by British Nuclear Fuels Limited, Windscale, Cumbria, UK, are found in sediment and biota of the Esk estuary ~10 km to the south. The site of the present investigation was at Newbiggin and the materials examined were suspended particulate debris samples at the sea surface, bottom sediments and some forms of biota collected in September 1977. It is shown here that hot particles (defined as small volumes of material emitting α particles recorded in a dielectric detector as dense clusters of tracks from a common origin) found in the estuary are likely to be original effluent debris derived from the processing of Magnox uranium fuel elements and not formed *in situ* as a result of natural processes common to the estuary.

Methods of analysis described elsewhere^{1–4} use a new dielectric α -track detector, CR-39 (ref. 5), in association with conventional chemical separation techniques and α -particle spectrometry using surface barrier detectors. The CR-39 method involves placing a sample in contact with a sheet of detector and after a suitable period of exposure the α particles recorded are developed by etching at 80 °C in 6.0 M NaOH for 3 h. After etching, the detector is viewed with the naked eye and α tracks associated with hot particles can be easily observed against a background of randomly distributed tracks; analysis of α -particle track distribution is then determined using a conventional light microscope with $\times 5$ or $\times 16$ objectives and $\times 10$ oculars; quantitative analysis of track densities is determined using a Quantimet image analyser.

In the Esk estuary (at the Newbiggin rail viaduct), after slack water and when the flood tide is just starting, the water becomes very turbid³; for a short period of time (15–45 min depending on the energy of the tide), fine-grained (<100 μ m) bottom deposited silts become resuspended into the water column (0.1–0.5 m deep) and just reach the surface, although in calm water conditions the top ~1 mm of water is often clear. In calm conditions the paper side of a sheet (30 $\times$ 30 cm) of Whatman

Data obtained following chemical separation and surface barrier α spectrometry.

Benchkote is touched onto the sea surface, just penetrating the clear surface layer of water if present, to which particulates recently resuspended into the water column adhere and are removed. Visible swirls of particulate debris present on the sea surface are retained by this technique as shown in Fig. 1a. Recently exposed bottom sediments are sampled similarly and if no pressure is applied to the paper, only the top layer of sediment (~ 1 mm) is removed. The Benchkote is then allowed to dry until just damp when it is placed against a sheet of CR-39 and exposed for between 2 h and 10 days. After the detector is etched two features are visible to the naked eye (Fig. 1b); first, the presence of diffuse opalescent markings which reproduce the macrostructure of the adhered sediment, and second, randomly distributed white spots ($<100 \mu\text{m}$ mean particle diameter) which represent the intense activity originating from hot spots. The position of the hot particles in the detector is noted and the corresponding site on the Benchkote identified. A small area of Benchkote enclosing a hot particle is then cut out; typically the level of diffuse activity associated with the area of paper removed is insignificant and all the activity originates from the hot particle. Briefly the following analytical techniques are then used. (1) The total number of α tracks from each separated particle is determined using the Quantimet analyser calibrated for α -particle detection efficiency against a standardized zinc sulphide screen counter⁴. When the track density is too intense with the result that individual tracks cannot be recognized, the total activity of the particle is determined by the zinc sulphide screen method; typically particle activities are between 0.1 and 3 pCi for total α emissions. (2) The hot particle attached to the Benchkote is then mounted in an energy calibrated surface barrier α spectrometer and the α spectrum determined. In the samples investigated so far ($n=28$), four of the spectra were partially degraded; these particles were dissolved in hot hydrochloric acid together with ^{236}Pu and ^{243}Am yield monitors, the detrital Benchkote removed and the leachate, after adjustment to pH of a plating solution, electroplated onto a polished stainless steel planchet. The total α activity recorded after electroplating agreed with that obtained by the zinc sulphide method and validates hydrochloric acid being used instead of nitric acid³ as a leaching agent to reduce the degradation of the Benchkote filter paper. None of the particles examined gave a totally degraded α spectrum and using the procedures described by Evans⁶ individual energies were identified. α -particle composition of the particles varied considerably; Pu and Am were always present, curium radionuclides were not always present; in six samples low energy emissions at ~ 4.8 meV and 4.2 meV were

observed and are tentatively identified as originating from $^{234}\text{U} + ^{237}\text{Np}$ and ^{238}U respectively.

When electroplating techniques are used without prior chemical separation of Pu and Am, because of energy overlap the radionuclides determined are $^{239+240}\text{Pu}$, $^{238}\text{Pu} + ^{241}\text{Am}$, $^{243+244}\text{Cm}$ and ^{242}Cm ; compared with standard chemical techniques³ no separation of ^{238}Pu from ^{241}Am is obtained. To convert the data into conventional terms the ^{238}Pu component had to be identified. Using chemical separation methods, together with published data, a $^{238}\text{Pu}/^{239}\text{Pu}$ ratio of 3.9 ± 0.3 determined on a large number of sediments and biota collected in September 1977 from the area, was used to determine the ^{238}Pu component of the $^{238}\text{Pu} + ^{241}\text{Am}$ α -spectra peaks. The activity of individual α emitters from Pu and Am was then calculated in terms of the percentage abundance for total Pu (α) and Am; the data are given in Table 1 and Fig. 2 and show that although the mean Pu/Am ratio for sediments and biota of the area is 1.1 ± 0.2 , the sea surface particulates showed a much greater range (Pu/Am, 3.2 ± 3.0) with a distinct trend towards an enrichment in Pu; none of the samples was significantly enriched in Am. A preliminary examination of hot particles ($n=10$) from the top 10 cm of deposited sediments gave a Pu/Am ratio of 0.9 ± 0.2 ; however, the morphology of these particles differs from those collected near the sea surface and will be discussed elsewhere. Note, however, that there are fewer hot particles present in buried sediments, and the specific activity is less. Data for *Fucus vesiculosus* indicates some degree of Pu enrichment which may be related to the entrainment of particles on fronds³.

In the absence of any quantitative data which describes the isotopic composition of transuranics, together with their chemical and physical form in fresh effluent released by BNFL, they cannot be identified in the Esk. However, circumstantial evidence allows some interpretation of the data. Using data presented by Nair⁷ it is calculated that the specific α radioactivity of aged Magnox fuel is $\sim 0.2 \text{ Ci g}^{-1}$. Measurement of particle size, using a technique based on the diameter of hotspots⁴ shows that the highest activity is usually associated with particles with a mean particle diameter of $<20 \mu\text{m}$; assuming that the density of these particles is ~ 10 they would have a maximum total α activity of $1\text{--}10 \mu\text{Ci g}^{-1}$, and therefore they do not consist of unprocessed uranium fuel. In the Esk estuary undisturbed sediments contain significant levels of short-lived radionuclides such as $^{95}\text{Zr-Nb}$ and ^{242}Cm , hence seaborne transit times for effluent from the outfall to the Esk are rapid enough for short-lived radionuclides to reach the area; indeed the estimated transit time is $<1\text{--}3$ months⁸, hence the presence or absence of water transported particulate debris at any single sampling time will depend on the previous weather conditions

Fig. 2 Photograph and direct α spectra for a hot particle containing Pu, Am and Cm radionuclides sampled at the sea surface.

Table 2 Mean monthly discharges (Ci yr^{-1}) for Pu and Am α radioactivity) from the uranium reprocessing plant together with Pu/Am ratios⁹

Year	$^{238}\text{Pu} + ^{239+240}\text{Pu}$	^{241}Am	Pu/Am
1977	984	96	10.3
1976	1272	324	3.9
1975	1200	984	1.2
1974	1248	3192	0.4

common to the region. Table 2 provides data for the Pu/Am ratio, derived from mean monthly discharge data which, in 1977⁹ was 10.3; in previous years it was significantly lower. The 1977 Pu/Am ratio for Esk sediments and biota (see Table 1 and Fig. 3) can be matched with 1975 releases, thus requiring a delay of ~2 yr before they become characteristic for the Esk. No data are available for the monthly discharges of Pu or Am released in the effluent, but from data presented by Baxter¹⁰ it seems probable that maximum releases occur during September–December of each year. Other data³ show that it was not until 1979 that sediment and biota of the Esk estuary showed enhanced levels of Pu, supporting the concept of a delay period ~2 yr before 1977 effluents became dominant in the region. Recently¹¹ it has been suggested, on the basis of derived sedimentation rates for Esk sediments, that there is a finite time lag of 2–3 yr between the plutonium discharges from BNFL and the arrival of plutonium in these sediments. Fundamental differences exist in the determination of the apparent time lag and are discussed elsewhere¹². Hence on this basis surface sediment of the Esk in 1977 would not be expected to reflect isotope ratios for current releases; through rapid transport of suspended particulates in the water column such debris could be present but its contribution to bulk deposited surface sediments would be small and difficult to identify. Note that, compared with sediments, uptake of Pu and Am by biota would be expected to reflect isotope ratios in seawater common to an area when the samples were taken.¹³

Six of the spectra obtained from the hot particles showed the presence of low energy emissions at 4.2 MeV and 4.8 MeV; for other samples the energy cutoff below the $^{239+240}\text{Pu}$ peak was sharp. These energies could arise from $^{234}\text{U} + ^{237}\text{Np}$ and ^{238}U . In 1978, 16 Ci of ^{237}Np was discharged by BNFL¹⁴ (no data are available for 1977) which should be detectable as it is similar to the discharge level for ^{242}Cm (15 Ci); it is assumed that ^{237}Np has always been a component of the BNFL effluent. Recent measurements confirm the presence of ^{237}Np in Esk silts at levels comparable with those found for Cm radionuclides. ^{237}Np in *Porphyra* from Sellafield, Cumbria is reported¹⁶ at a similar level to the ^{242}Cm abundance. Use of the delayed neutron method for uranium assay has shown² that in spite of a discharge of considerable quantities of uranium in BNFL effluent (for example, 10,936 kg in 1977)¹⁴ the levels for uranium in the Esk sediments are normal. Recent measurements¹⁵ have shown that the isotopic composition of uranium in Esk sediments does not show the presence of significant levels of depleted uranium despite problems associated with the production of ^{234}U from the decay of ^{238}Pu . However, the hot particles from surface water of the Esk seem to contain α emitters which would be compatible with the presence of U and ^{237}Np . The spectra do not contain ^{226}Ra or daughter products or thorium isotopes which could be attributed to natural sources. Therefore, the presence of the (U–Np)–Pu–Am–Cm radionuclides in some hot particles is interpreted as evidence that they represent original effluent materials. The lifetime for uranium-bearing particles in the sea is not known. A 4×0.5 mm uranium rod placed in seawater (oxygenated or reduced) decomposes within a few weeks to give dissolved species and finely disseminated uranium oxides which then slowly dissolve. It seems unlikely that any uranium-rich particle would survive intact for very long in the sea, thus they are unlikely to be present in deposited sediments, but could occur in the water column as a result of recent transport.

Uranium behaves in a conservative manner in seawater and using levels for ^{137}Cs (also conservative) in seawater off Windscale as a measure of effluent levels, it is calculated that if the 1977 discharges of U were totally dissolved in the sea this would give rise to a concentration of $0.03 \mu\text{g U l}^{-1}$ for offshore water, and $0.1 \mu\text{g U l}^{-1}$ for near-shore water, which would be difficult to detect in the presence of normal levels of $\sim 3 \mu\text{g U l}^{-1}$ for seawater².

Spent Magnox fuel rods are usually kept submerged in tanks held at pH 11.5, containing only trace quantities of Cl^- , CO_3^{2-} and SO_4^{2-} ions to prevent solution of the Magnox; usually imperfection and impurities cause some uranium fuel loss and this accumulates on the bottom of the tanks. Before recent improvements in waste treatment, the final low activity tanks were maintained at pH 2–3 which would precipitate iron, present as a contaminant, and coprecipitate the actinides¹⁷. Before discharge into the sea the effluent is treated with ammonium hydroxide which will predispose any remaining actinides in solution to assume less soluble forms (that is, colloids). Magnesium derived from the Magnox cladding is also likely to be present in the effluent. The released effluent has a complex composition and apparently contains particulate phases, some of which would dissolve in the sea (when dispersed) according to individual compositions. Radionuclide compositions of particles found in the Esk are similar to those of the original effluent before discharge, therefore are highly unlikely to have been formed *in situ* in the Esk. In the sea, magnesium hydroxide particles are likely to dissolve slowly while labelled iron particles would be transported further, and then become subject to solution processes in the organic-rich surface sediments of the Esk as a result of geochemical recycling. In the Esk interactions with freshwater and flocculation processes which occur at the salt–freshwater interface would assist dissolution of particles.

Dissolution of hot particles is supported by the form of the particulates. Hot particles with well defined form such as shown in Fig. 2 have been found in surface sediment and water, but are not always associated with the low-energy α emitters. In buried sediments occasional hot particles are present, but usually of lower activity. They often tend to have dimensions of ~ 10 (a and b axis) $\times 30$ (c axis) μm and would not be inconsistent with

Fig. 3 Ratio Pu/Am for sea surface particulates and other material (see Table 1).

the gradual solution of the surface water particles shown in Fig. 2. The hot particles associated with particulate matter sampled at the sea surface, and hence available for transfer into marine aerosols, have a mean particle diameter suitable for entry into the lung of man. In relation to potential health hazards to man the levels of currently released radionuclide effluents may be of more concern than those retained in older sediments where hot particles are less abundant and a diffuse distribution of α activity is more common, possibly reflecting redistribution as a result of geochemical recycling. Apart from the release of transuranics in effluent into the sea there is also a need to consider releases from the BNFL stacks and from the uncovered uranium fuel rod cooling ponds. Cambray and Eakins¹⁸ have shown that Pu is present in soils up to ~10 km from the Cumbrian coast and is either derived from direct emissions from Windscale or indirectly from the sea. Gorham¹⁹ has shown that within the region, up to a distance of at least 51 km from the coast, almost all the sodium and chloride ions in tarns (altitude 15–275 m) is derived from sea spray. Cambray and Eakins noted a correlation between Na and Pu and favour the sea surface as a major source for the Pu. Apart from the transport of conservative species of Pu and Am in droplets of seawater in marine aerosols the possibility exists for entrainment of the small sea surface hot particles which I have also found in soils, lichens and one ombotrophic peat inland from the coast. So far their distribution has not been evaluated because of difficulties in developing an acceptable programme of valid statistical sampling of such diffuse distributions.

Using conventional air sampling methods Pattenden *et al.*²⁰ note that Pu isotopes, ²⁴¹Am and ¹³⁷Cs are present in airborne and deposited material in west Cumbria in excess of the quantities expected for nuclear weapon tests. Excess actinides are considered to be derived from sea-spray and surf, but based on measurements of ¹³⁷Cs this cannot be accounted for by transfer of bulk seawater in the form of droplets. They note that conventional sampling methods are not efficient for samples with a mean particle diameter of >20 μ m because the inertia of large particles limits an ability to follow a moving air-stream. Using the CR-39 method I have observed that while the highest specific activity of resuspended air and sand particles is usually associated with those of a mean particle diameter of <20 μ m, there is an abundance of uniformly-labelled large particles which consist of coated sand grains (mean particle diameter 100–300 μ m) and ferruginous flocs¹⁵. In an examination of ~1,000 particles from the Esk region (resuspended silts, rocks, lichens) only one ~500 μ m particle was found to have a specific activity comparable with the sea-surface hot spots. The contribution of diffuse labelled large particles to sea-surface type hot particles is being investigated and is likely to be significant. CR-39 is capable of identifying the distribution of the hot particles on foliage and the surface of soils distant from Windscale and such a programme has been implemented. Because of the considerable uncertainties in even measuring maximum permissible levels of Pu in the human lung it would be useful to determine the distribution and composition of these hot particles in Cumbria and adjacent areas and evaluate their importance to man.

I thank R. J. Clifton and P. J. Moore for useful discussions. The Institute for Marine Environmental Research is a component of the Natural Environment Research Council.

Specific acyclic isoprenoids as biological markers of methanogenic bacteria in marine sediments

S. C. Brassell, A. M. K. Wardroper, I. D. Thomson, J. R. Maxwell & G. Eglinton

Organic Geochemistry Unit, University of Bristol, School of Chemistry, Cantock's Close, Bristol BS8 1TS, UK

The widespread occurrence of extended hopanoids in sediments and petroleum illustrates the importance of bacterial lipid contributions to geological materials¹. In archaeobacteria, however, hopanoids are absent¹; their role as structural components of biomembranes is fulfilled by acyclic isoprenoids^{1–5}. Recent studies^{2–6} of the lipid constituents of archaeobacteria have greatly extended the range of acyclic isoprenoid skeletons known in organisms (Fig. 1). In particular, isoprenoids with head-to-head linkages have been identified^{3–5}, and such compounds (for example, 3,7,11,15,18,22,26,30-octamethyldotriacontane, I) have been recognized in petroleum^{7,8} and as degradation products of Messel shale kerogen^{9–11}. Here we report the first recognition of 2,6,10,15,19-pentamethyleicosane (II), a known component of methanogens^{5,6}, in marine sediments of Recent to Cretaceous age (Table 1) and suggest that it and certain other acyclic isoprenoids may be used as biological markers for methanogens.

Until recently, the geologically occurring isoprenoid alkane, squalane (III), first characterized in a Nigerian oil¹², was generally believed to originate from geochemical reduction of squalene (IV). The discovery of squalane in several immature marine sediments^{13–17}, including Recent sediments^{13,14}, suggested that such a reduction must occur rapidly in the upper layers of sediment and therefore be microbially mediated. An alternative explanation is that squalane represents a direct input from organisms and the recent recognition of squalane in archaeobacteria^{5,6} supports this proposition. If, in general, archaeobacteria are important contributors of lipids to sediments, one would expect to find other compounds uniquely biosynthesized by these organisms in geological materials. One such compound seems to be 2,6,10,15,19-pentamethyleicosane, which has been found in methanogens^{5,6} but not in the other types of archaeobacteria, or in marine phytoplankton, such as diatoms, dinoflagellates, silicoflagellates and coccolithophores, which are major sources of sediment lipids. In addition, it has not been detected in zooplankton, although these organisms frequently contain another acyclic isoprenoid alkane, pristane, derived from chlorophyll¹⁸.

2,6,10,15,19-Pentamethyleicosane (II), squalane (III) and lycopane (V) were identified in the sediments by comparison of their mass spectra, obtained by computerized gas chromatography-mass spectrometric¹⁹ analysis of hydrocarbon fractions, with literature and/or reference spectra. Each sediment was extracted using ultrasonication; the total lipid extract was separated by TLC yielding a hydrocarbon fraction which, in some cases, was further separated by urea adduction. The mass

Fig. 2 Gas chromatogram (GC) of the branched/cyclic hydrocarbons of a Pleistocene diatomaceous clay/silty claystone (DSDP Leg 57, sample 57-440B-8-4; Table 1) from the Japan Trench. Peaks: A, pristane; B, 3-methylheptadecane; C, phytane; IX, phytanes; D, 4-methyloctadecane; X, 2-methyloctadecane; E, $C_{25}H_{44}$ bicyclic alkadiene of unknown structure^{44,45}; II, 2,6,10,15,19-pentamethyleicosane; F, tetracyclic alkane related to lupane^{46,47}; III, squalane; G, hop-17(21)-ene; H, neohop-13(18)-ene; J, neohop-12-ene; K, fern-7-ene; L, 17 β H,21 β H-homohopane. GC conditions: 20 m OV-1 wall-coated glass capillary, programmed from 50 to 265 °C at 4 °C per min after splitless injection at ambient temperature. A prominent feature of the GC trace is the apparent 'hump' which in crude oils and polluted sediments would be attributed to a background of thermally matured hydrocarbons. In this sample, however, the concentrations of other individual hydrocarbons (for example, steranes and hopanes) commonly associated with the 'hump' is small; hence, it is uncertain whether it represents highly biodegraded thermally matured or natural inputs or, alternatively, shipboard contamination with drilling lubricant.

spectrum of 2,6,10,15,19-pentamethyleicosane (II) is distinct from those of VI (2,6,10,14,18-pentamethyleicosane) and VII (2,6,10,14,19-pentamethyleicosane) for several reasons^{6,16,17}, particularly the absence of m/z 253 in II. The assignments of squalane (III) and lycopane (V) were corroborated in a number of cases by gas chromatographic co-injection with authentic standards. Components were quantified from their gas chromatographic responses.

The recognition of 2,6,10,15,19-pentamethyleicosane (II) in three marine environments where methanogens have been recognized and/or high concentrations of methane have been found (Table 1) suggests the working hypothesis that this alkane marks a contribution of lipids from methanogens to marine sediments. An isomer, 2,6,10,14,18-pentamethyleicosane (VI), recently found in thermoacidophilic bacteria⁶, has previously been reported as a constituent of various shales²⁰, oils^{7,8,21-23} and sediments²⁴. The occurrence of squalane (III) may also reflect methanogenic activity in these marine sediments (Table 1), although this compound has been found in both thermoacidophilic and methanogenic bacteria⁶. However, significant inputs to marine sediments from thermoacidophilic and halophilic bacteria are improbable, although such archaeobacteria may be important sources of lipids in other environments, for example in the Dead Sea²⁵. Lycopane (V) is another isoprenoid alkane found in significant quantities (see Table 1) in Recent^{14,16,17} and ancient²⁶ marine sediments. It could be formed by diagenetic reduction (perhaps microbial) of lycopene (VIII)^{14,16,17} but, by analogy with squalane, a direct bacterial origin is also possible. Indeed, the Recent sediments in which lycopane has been reported are all environments where methanogenic activity has been documented (Table 1).

In older and more deeply buried sediments, after methanogenic biological activity has ceased, the presence of methane and the lipid signatures may attest its former existence. Hence, in the Pleistocene to Miocene sediments of the Cariaco and Japan Trenches, the presence of methane in high concentrations²⁷⁻²⁹ and the recognition of the isoprenoid alkanes II and III (Table 1) indicate past biological methanogenesis in these sediments. In more mature sediments the presence of methane alone cannot be used as an indicator of former methanogenic biological activity. For example, the methane in the Moroccan Basin turbidites (Table 1) is thought to be migrated rather than

Detailed analyses of the lipid distributions of II, III and V are reported elsewhere^{15-17,36-38}. ND, not detected; NA, not analysed; +, minor amounts not quantified; Tr, trace (<0.1 ng per g) amounts of component present.

*CH₄ found (90-2,926 and 10-91 ng per g) in subsections of sediment cores up to 2.3-m depth from nearby locations (22°47'S, 14°26'E and 23°14'S, 14°01'E, respectively) and attributed to methanogenic bacterial activity²⁷.

†CH₄ occurs in Site 481 sediments³⁹ and is abundant (2,190-7,520 ng per g) in the subsurface sediments (2.51-3.45 m) collected about 8 km to the north-east (27°23'N, 111°27'W), with $\delta^{13}\text{C}$ values (-68.8 to -73.5) indicating its biogenic origin⁴⁰. Methanogenic bacterial activity has been recognized in an overlying sample (64-481-1-2) from 2.9-m depth⁴¹ and shallow sediments (0.5-1.7 m) from a nearby site (27°09'N, 111°08'W)⁴².

‡CH₄ detected in gas pockets to 175-m depth at Site (147 (ref. 28) and found in high concentrations (>200 ng per g) in other shallow sediments (0-1.6 m) from the area²⁷. Methanogenic bacteria have been isolated from nearby surface sediments within the western basin of the Trench (10°37'N, 65°26'W)⁴³. Lycopane has also been recognized in shallow sediments (0-5.5 m) from the eastern basin (10°32'N, 64°39'W)¹⁴.

§Data for adjacent samples from ref. 29.

||Data for adjacent samples from ref. 30.

indigenous gas³⁰. Hence, the presence of the acyclic isoprenoid alkanes provides a better geological record of biological methanogenesis than the presence of methane.

In the Holocene sediments the differences in the relative proportions of II, III and V may result from dissimilar methanogen populations, as methanogen lipid compositions are species dependent^{5,6}. In addition, the variability in their concentrations in these sediments may reflect the intensity of biological methanogenesis. The deeper and older sediments tend to contain lower concentrations than do the Holocene sediments (Table 1), partly because other microorganisms may have degraded the methanogenic lipids. Other factors may be involved, for example, the known flux of terrestrial material in the Japan Trench sediments and Moroccan Basin turbidites may have diluted the methanogenic lipid signature³¹. Such factors, however, tend to restrict rather than invalidate the use of acyclic isoprenoid alkanes as biological markers of methanogens. Although the Cretaceous samples contain only low concentrations of II and III, the mere presence of these compounds is presumptive evidence for methanogenesis at the time of deposition. Methanogenic bacteria seem, therefore, to be important contributors of lipids to deep-sea sediments at present and in the geological past, presumably as a result of their activity at appropriate E_h (redox potential) zones in the sub-bottom sediments. The significance of archaeobacterial contri-

butions to petroleum has already been demonstrated^{7,8}, but present evidence suggests that specific acyclic isoprenoid alkanes may also be environmental indicators. That they are important constituents of sediments can be seen from their relative abundances in branched/cyclic (urea non-adducted) hydrocarbon fractions (Fig. 2). Future investigations should include stereochemical determination of these acyclic isoprenoid alkanes in sediment extracts, as their configurations will reflect their origin and diagenetic history^{32,33}, together with studies of the stereochemistry of these compounds in methanogenic bacteria.

Other isoprenoid hydrocarbons may also arise from methanogens. Squalene (IV) and phytanes (IX) have been found in young marine sediments^{16,17}, but could originate from other sources—for example, phytanes may be products of phytol or dihydrophytol diagenesis³⁴. Thus, these compounds cannot generally be regarded as definitive indicators of archaeobacterial inputs to sediments. An additional group of acyclic hydrocarbons biosynthesized by archaeobacteria⁶ is branched alkanes (for example, 2-methyloctadecane, X); these compounds also occur in deep-sea sediments¹⁷ (Fig. 2). Indeed, most of the prominent branched/cyclic hydrocarbons of the Japan Trench sediments (Fig. 2) can be ascribed to bacterial origins. In view of their recent recognition in a bacterium³⁵, the presence of hop-17(21)-ene (G), neohop-13(18)-ene (H) and fern-7-ene (K) in

immature sediments probably reflects autochthonous inputs from bacteria rather than terrestrial inputs from ferns¹⁵⁻¹⁷. It seems likely, by analogy, that neohop-12-ene (J) is also of bacterial origin.

Thus, there is growing evidence in support of major bacterial lipid inputs to marine sediments. The presence of components which seem to be biosynthesized uniquely by methanogens, such as 2,6,10,15,19-pentamethyleicosane, suggests that these bacteria are important contributors of alkanes to marine sediments.

We thank the NERC (GR3/2951 and GR3/3758) and NASA (subcontract from NGL-05-003-003) for funding. A.M.K.W. and I.D.T. acknowledge studentships from the SRC, S.C.B. from the NERC. We thank Dr R. S. Oremland for information about methanogens in Gulf of California sediments, Mrs A.P. Gower for technical assistance, and colleagues at Bristol for access to extracts^{15,19}. Sediment samples were provided by the Deep Sea Drilling Project (JOIDES), with the exception of the Walvis Bay sediment, which was kindly supplied by Dr R. J. Morris.

Anomalous ¹³C depletion in early Precambrian graphites from Superior Province, Canada

M. Schoell

Bundesanstalt für Geowissenschaften und Rohstoffe, Stilleweg 2, 3000 Hannover 51, FRG

F.-W. Wellmer*

Metallgesellschaft AG Reuterweg 14, 6000 Frankfurt a.M., FRG

The carbon isotope composition of organic carbon is potentially, at least, a guide to the conditions in which and to the organisms by which it was formed. The isotopic composition of most Phanerozoic kerogens, measured as $\delta^{13}\text{C}$ values, lies within the range -20‰ to -30‰. Most (~65%) samples of Precambrian organic carbon, now represented by graphite and other forms of reduced carbon, have isotopic ratios within the same range, but in others the concentration of ¹³C is significantly depleted by as much as 10‰. The causes of this depletion have an obvious bearing on the conditions of life in the Precambrian. Here we report the results of our measurements of samples of graphite from the Archean of the Superior Province of Canada, one of which being the most depleted in ¹³C ever found in the Precambrian. We explain this ¹³C depletion by organisms in some areas living on CO₂ oxidized from CH₄ that has been formed by methane-producing bacteria in Precambrian stratified seas.

Some 35% of the Precambrian graphite samples measured have ¹³C concentrations which lie outside the Phanerozoic range. Enrichment has usually been explained by the preferential loss of ¹²C during metamorphism¹⁻⁴, but depletion is harder to account for. It has been suggested that depletion may be a consequence of higher CO₂ partial pressure in the Precambrian^{5,6} or may have come about because of the predominance of lipids depleted in ¹³C in Precambrian organic matter⁷.

All ¹³C/¹²C ratios of graphite samples from the Archean of the Superior Province studied so far were within the range of Phanerozoic kerogens⁸. They were from graphites associated with sulphidic and oxidic iron formations and their transition zone. Iron formations are commonly intercalated between volcanoclastic sediments, less common between volcanic flows, and closely associated with cherts, carbonaceous argillites and graywackes. Iron formation horizons can often be followed for tens of kilometres indicating extensive sedimentary basins; the Michipicoten area of northwestern Ontario is a typical example. The isotope ratios of graphites from iron formation horizons of this area all lie in the range -20 to -28‰ (ref. 8). This range also covers the only sample of this report collected in a similar sulphidic iron formation environment of the Savant Lake-Sturgeon Lake area in northwestern Ontario (102 PQ, Table 1).

The other nine samples on which we report were collected from drill holes in a different type of sulphidic graphitic sediments which occur within the volcanic piles themselves. These sediments consist of thin layers of graphitic sulphidic tufts or interflow sediments with strike lengths of the order of only 100-1,000 m. In contrast to the large sedimentary basins with extensive iron formations these short graphitic horizons are imbedded in local depressions the size of which is indicated by the strike lengths of the graphite horizons derived from airborne and ground geophysics. One of these horizons extends over a distance of 1,400 m but all others stretch only a few hundred metres indicating rather small pools.

The samples were crushed and treated with diluted acid to remove possible carbonate material, and then burned at temperatures of 900°C in a stream of pure dried oxygen using a copper oxide catalyst. The resulting CO₂ was analysed for its carbon isotopic composition with a triple collecting mass-spectrometer (VG 903). Usual corrections were applied and the isotopic composition is reported as δ -value versus the PDB-standard. All samples were processed twice. The reproducibility as determined from double measurements is $\pm 0.2\%$. The NBS graphite standard has been determined at $-28.2 \pm 0.1\%$. (δ -values are defined as relative deviations from the PDB standard where $\delta^{13}\text{C} = (R_{\text{sample}}/R_{\text{standard}} - 1) \times 1,000\%$ where R is the isotope ratio $^{13}\text{C}/^{12}\text{C}$.)

* Stratigraphic distance to top of volcanic pile.

† Length of graphite horizons.

‡ Thickness of graphite horizons.

§ Two graphite horizons in the same drill hole separated by a 15 m stratigraphic section.

|| K 1 and K 10 same graphite horizon 60 m apart along strike.

¶ Horizon of K 2, 700 m stratigraphically lower than K 1 and K 10.

The volcanic and sedimentary host rocks of the graphite horizons have been metamorphosed in greenschist facies conditions. Typical mineral assemblages in the volcanics are chlorite, actinolite, epidote, albite, quartz and sericite. Samples A3/1, A3/2 and X-1 are from the Abitibi-Wawa volcanic plutonic belt for which radiometric data indicate an age of $\sim 2,750$ Myr; all other samples are from the 2,800-Myr old Wabigoon volcanic plutonic belt^{9,10}. Our graphite samples come from bands and layers intricately intercalated with volcanoclastic sediments, indicative of their indigenous nature. Microscopic examination shows that graphites form flakes which are commonly oriented parallel to the schistosity; optically the flakes display a clearly visible pleochroism which proves the graphitic nature of the carbonaceous matter.

Table 1 gives the results of our isotope analyses and some field data, obtained from exploration drilling. The geological position of the graphite horizons is estimated from their stratigraphic distance to the top of the volcanic pile which varies between 1,200 and 0 m, mostly being 400–900 m.

Seven of the 10 samples analysed revealed $\delta^{13}\text{C}$ values between -21 and -27% —the normal range within the spread of data of many other Precambrian samples (Fig. 1). Three samples show significant depletion in the heavy isotope with $\delta^{13}\text{C}$ values between -35% and as low as -43.8% ; this value is among the lowest ^{13}C concentration ever reported for Precambrian reduced carbon. The field data indicate a common geological setting even for those localities which yielded the anomalously low ^{13}C graphite data. Sample K2 from the Onaman Lake area in northwestern Ontario with an extremely low $\delta^{13}\text{C}$ value was taken in the same volcanic pile only 700 m away from two normal value samples (K1 and K10).

Anomalous ^{13}C depletion ($\delta^{13}\text{C}$ less than -30%) in Precambrian organic matter has been reported previously^{4,5,12,14,16} (Fig. 1). But some of the values shown in Fig. 1 are not indicative of the primary source. For example, $\delta^{13}\text{C}$ values of -37.01 and -39.1% respectively have been reported for the so-called anthraxolites⁴. Stringers of visible carbon in limestones were also found to be depleted in ^{13}C ($\delta^{13}\text{C} \approx -37$ to -41%) as

compared with disseminated carbon which had 'normal' values around -26 to -33% (ref. 16). Secondary effects must have been operative to form both the anthraxolites and the stringers which forbids any conclusion as to their original isotopic composition. Such secondary effects are ruled out for our graphite samples (data set 1 in Fig. 1). They are undoubtedly of syngenetic nature which is indicated by the above described primary sedimentary features.

Thus the anomalous $^{13}\text{C}/^{12}\text{C}$ isotope ratios indicate special environmental conditions which must have prevailed in some of these small depressions. These special conditions are assumed to have prompted the organic species to incorporate the ^{12}C -isotope more readily.

We discarded the theory that in some pools specific assemblages of organisms had different isotope fractionations when assimilating carbon. Also, we consider it unlikely that various differing metabolic systems were involved.

The change of the isotopic composition of the carbon source is therefore considered in the following as the process which may easily explain such a large change in organic $^{13}\text{C}/^{12}\text{C}$ ratios as we observed or even larger changes. In all cases the formation of graphite is closely interrelated with the occurrence of sulphidic sediments indicating areas of hydrothermal activity. The discharge of hydrothermal brines into morphological depressions is likely to cause a stratification of waters as described for the Red Sea brine pools, the Lake Kivu or more recently from below the Gulf of Mexico¹⁷⁻²⁰. The brines prevent vertical mixing and thereby act as traps for organic debris. Methane can form in such environments and may have become trapped in the stratified waters. The formation of methane by bacteria is the only geochemical process known to bring about appreciable ^{13}C -depletion (typical $\delta^{13}\text{C}$ values are around -60 to -80%). Methane may become oxidized to CO_2 when appreciable residence times within the stratified waters allow CH_4 oxidizing organisms to grow²⁴. The CO_2 from methane oxidation is even more depleted in ^{13}C than the methane²¹ and its ^{13}C concentration can range from -70 to -90% . Such ^{13}C -depleted CO_2 would then be admixed to CO_2 which may have been derived

Fig. 2 Hypothetical explanation of the ^{13}C depletion in Precambrian organic carbon. Stratified waters are traps for methane which is bacterially produced in the stratified waters. Oxidation in the sediment or at water interfaces would generate ^{13}C depleted CO_2 as a carbon source for metabolizing eukaryotic biota.

from hydrothermal solutions or from air CO_2 to form a carbon reservoir, depleted in ^{13}C (Fig. 2). Oxidation of CH_4 to CO_2 does not necessarily need free atmospheric oxygen because anaerobic methane oxidation is performed in nature by sulphate reducers^{22,23}:

and sulphate ions are likely to have been available from seawater or hydrothermal brines.

Methane-producing bacteria are ubiquitous in nature and must be regarded as one of the earliest species of organized life on Earth. They may, therefore also have played an important role in Precambrian times. The above model, summarized in Fig. 2, attempts to explain the as yet not understood variability of $^{13}\text{C}/^{12}\text{C}$ ratios in Precambrian reduced carbon. The extent of ^{13}C depletion would depend on the mixing ratio of normal CO_2 and CO_2 oxidized from CH_4 . An addition of 20% oxidized CO_2 to a CO_2 pool with an initial $\delta^{13}\text{C}$ of -7% would change the organic carbon $\delta^{13}\text{C}$ by 14% in favour of the light isotope, that is, the isotopic composition of -43% found in one graphite sample would have required an addition of $\sim 25\%$ of CO_2 which has been produced from CH_4 oxidation. Whether or not CH_4 and the CO_2 oxidized from it enters the CO_2 pool in which organic matter is metabolized depends on the specific situation of each basin. In shallow waters without stratification methane escapes without being oxidized; in well stratified waters methane is oxidized during diffusional exchange at density interfaces or alternatively at the sediment-water interface²⁰. Note that a relatively large fraction of our graphite samples (short non-iron formation horizons within the volcanic pile) is depleted in ^{13}C (three out of nine). In the graphites from large basins, no ^{13}C -depleted samples were found⁸. This may be due to differences in basin dimensions: in small basins stratified waters are more stable than in large basins.

The above processes are not necessarily confined to the small basins of the Archean of the Superior Province. They could have operated in other Precambrian areas where anomalous ^{13}C -depleted reduced carbon is found. The bulk of reduced Precambrian carbon has the same ^{13}C concentration as Phanerozoic kerogens and the ^{13}C -depleted reduced carbon might be explained by local effects. This reasoning argues against the interpretation of low ^{13}C concentrations in Precambrian organic matter as being indicative of special conditions in the Precambrian as compared with Phanerozoic times. The completely different environmental conditions (low O_2 partial pressure) obviously had not affected the basic processes of CO_2 assimilation.

We thank Teck Explorations Ltd for permission to publish the data.

Population density and body size in mammals

John Damuth

Committee on Evolutionary Biology, University of Chicago,
1103 E. 57 Street, Chicago, Illinois 60637, USA

There seems to be an inverse relationship between the size of an animal species and its local abundance. Here I describe the interspecific scaling of population density and body mass among mammalian primary consumers (herbivores, broadly defined). Density is related approximately reciprocally to individual metabolic requirements, indicating that the energy used by the local population of a species in the community is independent of its body size. I suggest that this is a more general rule of community structure.

Figure 1 shows the logarithm of mean population density plotted against the logarithm of mean adult body mass for 307 species of mammalian primary consumers. As far as possible, the density values represent 'ecological' densities, that is, those which apply to the habitat area actually used by the species. The

relationship is linear, with a slope of -0.75 , and species densities seem to be restricted to varying within about one order of magnitude from the value predicted by the regression line.

This analysis combines data from a wide variety of habitats throughout the world, and it is important that we know whether this overall pattern accurately reflects that found within individual communities; few, if any, mammal communities have been completely studied. To obtain a representative sample, I extracted from my data those sets yielding densities of three or more species within the same habitat type; these 'constructed' communities are shown in Table 1, with regression statistics. They include representatives of almost the whole range of habitat structures and primary productivity levels encountered by terrestrial mammals. None of the individual slopes, which vary from -0.56 to -0.95 , differ significantly from -0.75 , and Levene's test¹ and an analysis of covariance² reveal no significant differences in variance about the regression, in slope, or in intercept. Pooling the data from the communities gives an estimated slope of -0.70 , which is not significantly different from the value obtained for the overall regression (t -test). Thus, the overall trend gives a reasonable representation of that which we are likely to find within individual communities.

Knowledge of population density scaling in communities allows us to consider the relative energy use of species among primary consumers of different sizes. Individual basal metabolic requirements are related to body mass by the power of 0.75 (refs 3, 4). Estimates of the metabolic requirements of free-living mammals in natural habitats roughly parallel basal requirements, but at a higher level, varying between ~ 1.5 and 3.0 times basal values^{5–13}. Thus they will also be related to body mass by the power of ~ 0.75 . The energy used by the local population of a species equals the population density (D) multiplied by individual metabolic requirements (R), which yields the following relationship to body mass (W): $DR \propto W^{-0.75} W^{0.75}$. The exponents of W cancel each other, which gives the important result that the amount of energy that a species population uses in the community is independent of its body size. No mammal herbivore species, on an ecological time scale, has an energetic advantage over any other solely as a result of size differences.

There are two important corollaries of this relationship. First, because secondary productivity for a given amount of assimilated energy is independent of body size in mammals (Kleiber's Law)³, it follows from the above that the secondary productivity of a herbivore species' local population, and hence the energy that it yields to the next higher trophic level, is also independent of body size. Second, the standing-crop biomass of a species (population density multiplied by body mass) is positively related to body mass by the ~ 0.25 power; this is a

Table 1 Habitat types and constructed communities

Community/habitat type	a	s.e.	r	b	n
Sonoran desert, USA	-0.63	0.16	-0.76	3.37	14

Northern hardwoods, USA*	-0.57	0.11	-0.98	3.11	3
Oaks and chaparral, USA*	-0.72	0.021	-0.99	4.83	3
Means of statistics	-0.74	0.20	-0.93	3.93	—
Pooled data from above regressions	-0.70	0.040	-0.86	3.71	109

Statistics are for standard least-squares regression equations: $\log D = a(\log W) + b$; s.e., standard error of the slope (a); r, correlation coefficient; n, number of species. Note that in the pooled regression, as some species are found in more than one habitat type, $n = 109$ includes only 92 separate species.

* Due to small sample size and/or a single point at one end of the size range, the individual values for these regressions are not very reliable.

Fig. 1 Population density (D) compared with the mean adult body mass (W) for 307 mammal primary consumers; each point represents one species. Density values for each species are the mean of the means from each locality from which data were reported for the particular species. (Data are from the literature for the years 1950–79, derived from 115 journals and numerous books, ~650 references in all.) The line represents the least-squares regression line, $\log D = -0.75 (\log W) + 4.23$; $r = -0.86$, standard error of the slope = 0.026.

quantitative measure of a qualitative relationship that has been known for some time but only sporadically appreciated¹⁴. Species of small mammals are able to produce, on average, the same amount of biomass over time as do species of large mammals, whereas at a given moment their standing-crop biomass is considerably less, because the population turnover rates and individual growth rates per unit weight of small species are much greater^{15–17}.

The widespread occurrence of an approximately reciprocal relationship between population density and individual metabolic requirements among mammalian herbivores suggests that a general principle is involved. The independence of species energy control and body size revealed by this reciprocal relationship implies that random environmental fluctuations and interspecific competition act over evolutionary time to keep energy control of all species within similar bounds. It is unlikely that the occurrence of competition among species of different body sizes is restricted to herbivorous mammals. Along with the ubiquity of allometric scaling of metabolic rate with body size⁴, this suggests that a reciprocal relationship, and particularly a value of ~ -0.75 , characterizes a broader range of taxa and trophic levels. These points will be discussed more fully elsewhere.

Competitive ability influences habitat choice in marine invertebrates

Richard K. Grosberg

Department of Biology, Yale University, 260 Whitney Avenue, PO Box 6666, New Haven, Connecticut 06511, USA

Patterns of distribution and abundance of sessile marine epibenthic invertebrates are controlled by three factors: (1) the presence and abundance of larvae which are competent to settle, (2) the choice of settling sites by recruiting larvae, and (3) the biotic and physical events occurring during and after settlement. Although there is much information on the distribution of larvae and seasons of recruitment^{1–3}, substratum selection^{4–6} and post-settlement events^{7–15}, very little is known of the ecological and evolutionary relationships between these factors^{5,16–18}. Natural selection acts on entire life cycles, thus information about these relationships is essential for understanding patterns of recruitment and survival. For example, sessile organisms can modify the course of post-recruitment events by selective settlement and directional growth¹⁹. Here, I present evidence that the larvae of several taxa of marine invertebrates avoid substrata where there is a high probability of death caused by a superior spatial competitor.

I found, as did Grave²⁰, that in the Eel Pond at Woods Hole, Massachusetts (USA), the two compound ascidians *Botryllus schlosseri* (Pallas) Savigny and *Botrylloides leachii* (Savigny) cover, by area, over 50%, and sometimes 100%, of hard substrata during the spring and summer. This period includes the season of recruitment for most other colonizers. Thus, settling larvae are likely to contact a botryllid ascidian at some time during their lives. A common result of contacts between colonists is overgrowth of one organism by another^{21–29}. In this way, overgrowth is a consequence of competition for space (and perhaps other resources³⁰), and therefore can be an important factor in the distribution and abundance of encrusting species.

B. schlosseri is the most successful overgrower (along with *B. leachii*) in the Eel Pond (Table 1) and is rarely overgrown by other species. As it is such an important member of the Eel Pond epibenthic assemblage (considering the post-settlement events of overgrowth and coverage), I investigated the effects of its density on the recruitment of other taxa.

B. schlosseri collected from the Eel Pond were placed in finger-bowls where they released larvae which were then transferred to 10-ml polycarbonate dishes. Two hours after settlement on the sides of the dishes, the juveniles were teased off and re-attached to 5 × 5 cm glass plates. I set up three densities of juvenile *Botryllus* with three replicates of each: (1) 15 regularly spaced *Botryllus* juveniles, with all subsequent botryllid settlement removed daily; (2) 5 regularly spaced *Botryllus* juveniles with all subsequent botryllid recruits removed daily; and (3) no *Botryllus* juveniles with daily removal of all botryllid recruits. Three additional glass plates which initially carried no juveniles, but on which all recruits were allowed to remain, served as controls.

Experimental and control plates were positioned horizontally in a Latin square arrangement³¹ below a floating dock at 1 m depth. The experiment was started on 20 July, 24 h after the larvae had been transplanted. The lower side of each plate (which carried the juvenile *Botryllus*) was censused non-destructively until 28 July on a daily basis—this allowed me to distinguish between failure to settle and all but the earliest post-settlement mortality.

Figure 1 shows the numbers of each species that settled on the glass plates. To determine if there were any differences between each of the three density treatments and the controls, the data for each species were analysed using the null hypothesis that

settlement was uniform in each case. χ^2 tests unambiguously placed the species in two groups: (1) selective species or those for which settlement was not uniform between treatments (Fig. 1a, all $P < 0.005$) and (2) non-selective species or those for which there were no significant differences in settlement between density treatments (all $P > 0.2$). When settlement on the plates carrying five *B. schlosseri* was compared with that on plates where all botryllids had been removed, settlement was uniform for all species ($P > 0.5$). On control plates, where cumulative *B. schlosseri* settlement reached 15 per plate on the third day of the experiment, settlement of selective species was intermediate between that on plates carrying 15 *B. schlosseri* and those carrying none or five juveniles. This implies that the threshold for detection of *B. schlosseri* by selective species lies somewhere between 5 and 15 resident *Botryllus* juveniles.

There is a clear relationship between patterns of recruitment and a species' susceptibility to overgrowth. The species which did not settle on plates where *Botryllus* number was 15 (selective

species) were also overgrown by *Botryllus* in 1,008 of 1,048 contacts (96.2%). These species are the first nine of Table 1. In contrast, those species which settled uniformly, regardless of *B. schlosseri* density (non-selective species), were rarely overgrown by *Botryllus* (171 of 961 contacts or 17.1%). These species include the remaining 10 of Table 1.

The mechanisms by which settlement is decreased for some taxa, but not for others, are unclear. Allelopathy^{22,32,33} cannot account for these results, for when selective species do settle on the plates (for example, at low *Botryllus* densities), they often settle immediately adjacent to the competitive dominant. In addition, because *Botryllus* cannot ingest particles as large as most recruiting larvae^{34,35}, selective predation does not explain the results. It is more likely that the settling larvae of some taxa can recognise the density of resident *Botryllus*, and reject substrata when that density exceeds a certain threshold.

Selective settlement has been observed in a number of taxa, but it is not understood which factors make particular substrata

Fig. 1 The cumulative settlement for all species which settled during the experiment. Bars represent the mean settlement for the three replicates of each density treatment and the controls. Lines indicate the range of settlement values. The plates were arranged in a Latin square so that plate position effects could be detected: the χ^2 analyses indicated that there were no significant differences between replicates, thus there were no plate position effects. Of the 60 transplanted larvae, only one died during the experiment. Any settler not immediately identified was allowed to grow after the term of the experiment until identification was possible. At the end of the experiment, none of the colonists covered $>2 \text{ mm}^2$, thus coverage was low. *a*, Data for species which showed a settlement effect at different *B. schlosseri* densities. These are termed selective species—this group includes four encrusting bryozoans, three tube-building polychaetes and two barnacles. All these species have feeding structures close to the substratum, thus easily obstructed by overgrowth. *b*, Data for those species which showed no significant differences in settlement at different *Botryllus* densities. These are termed non-selective species—this group includes four arborescent bryozoans, two stoloniferous hydroids, three solitary ascidians and two colonial botryllid ascidians. With the exception of the botryllids, all members of this group have elevated feeding structures and therefore are generally resistant to the effects of overgrowth (see refs 23, 28).

Table 1 Results of contacts between *Botryllus schlosseri* and the adults of the species which recruited during the period 20–28 July 1979

Overgrown	Wins	Ties	Total	Wins/total (%)	Losses/total (%)

<i>Styela clava</i>	2	95	97	2/97 (2.1%)	0/97 (0%)

These data were collected during the summer of 1979 from contacts between animals living on algae, floating docks, rocks and glass plates in the Eel Pond. All contacts were followed from their initiation until their resolution by overgrowth or mutual retreat. Total contacts equal wins + losses + ties. A win is scored when *Botryllus* overtops and kills >50% of a colonial organism, or entirely kills a solitary organism. A tie is scored when growth of both participants ceases along a contact, or when *Botryllus* simply grows around another colonizer without perceptible harm to either. Although *Botryllus* infrequently overgrows certain taxa, it is rarely overgrown itself by any taxa. Nevertheless, the canopies of arborescent bryozoans and hydroids sometimes shade underlying compound ascidians.

(or habitats) better than others. Notable exceptions include: (1) the gregarious settlement of some barnacles which apparently ensures cross-fertilization and viability of eggs^{6,33,36}; (2) the preferential settlement of predators, commensals and parasites near their prey, partners and hosts, respectively⁵; (3) the selection by some bryozoans and polychaetes of particular algae (or positions on these algae) which correlates with patterns of survival of juveniles and adults^{17,18,37}; and (4) the gregarious settlement of some arborescent bryozoans which enhances their interspecific competitive ability³⁸.

The results from the Eel Pond indicate that some larvae can distinguish substrata where post-settlement events are likely to kill them. Apparently, these larvae avoid encounters with the competitive dominant, *B. schlosseri*, by settling away from dense stands of it. In comparison, the larvae that do settle where *B. schlosseri* is abundant are those most immune to overgrowth by it. Taken together, the data illustrate that competition during the post-settlement phase of an organism's life cycle can strongly influence the evolution of habitat selection.

Fertilization potential in golden hamster eggs consists of recurring hyperpolarizations

Shun-ichi Miyazaki & Yukio Igusa

Department of Physiology, Jichi Medical School, Tochigi-ken 329-04, Japan

The fertilization potential, or activation potential, has been demonstrated in the eggs of various species¹, and it has been shown to block polyspermy in echinoderm^{2,3}, echinuran⁴ and frog⁵ eggs, but no studies have been reported of electrical phenomena occurring when mammalian eggs are fertilized. We report here the fertilization potential of golden hamster eggs *in vitro*. To correlate the change of potential with the interaction between sperm and egg, only one sperm was attached to each egg. We found that a sperm induces recurring hyperpolarizations, constituting a fertilization potential which differs from that in the eggs of other species.

Mature eggs were collected from the oviducts of superovulated females⁶ and freed from the surrounding cumulus cells and zona pellucida by sequential treatment with 0.1% hyaluronidase (~5 min at 23–26°C) and 0.1% trypsin (4–5 min) in medium used for rat eggs⁷. Removal of the zona allows sperm to reach the plasma membrane soon after insemination. Spermatozoa obtained from the cauda epididymis were activated with acrosome reaction by incubation in modified Tyrode solution containing 20% human serum⁸ and 1% bovine adrenal gland extract⁹ at 37°C for 4 h. All treatments and experiments were performed in a 0.4 ml drop of medium placed in a plastic Petri dish and covered with paraffin oil. A glass microelectrode was

inserted in an egg viewed in a phase-contrast inverted microscope and a small amount of the sperm suspension was added to the egg medium at 30–32 °C (final concentration 2,000–5,000 sperm per 0.4 ml). Electrode resistances were in the range 40 to 80 M Ω , and leakage current of a preamplifier was <2 pA. Each experimental egg was transferred quickly to sperm-free medium after withdrawing the electrode, and was incubated for 4 h to determine sperm entry by observation of male pronuclei.

The resting potential of unfertilized eggs averaged -29 ± 7 mV (mean $\pm$ s.d., $n = 120$), but 7% of the values were between -40 and -50 mV. The current–voltage relationship (I – V curve) was linear for potentials of between -100 and 0 mV, and the effective membrane resistance averaged 142 ± 65 M Ω ($n = 98$). The more negative resting potential tended to be associated with the larger membrane resistance, suggesting that there was a substantial leakage due to electrode impalement in most cases. The largest resting potential was -50 mV with a membrane resistance of 400 M Ω , which is estimated to be 66 k Ω cm ^{2} , assuming that the egg is a sphere of 72 μ m diameter.

Figure 1A shows the fertilization potential in the case of the severe polyspermy which usually occurs in zona-free eggs. The major potential change is a repetitive, transient hyperpolarization (H-response, HR) associated with an increase in membrane conductance. There was no observed HR during a 10-min recording before insemination. The first HR had the following characteristics: peak potential, -72 ± 8 mV (mean $\pm$ s.d., $n = 53$); duration, 14 ± 3 s; membrane resistance near the peak, 28 ± 9 M Ω . The membrane conductance became 4.5 ± 1.8 times larger than that just before insemination. Successive HRs differed in minor ways: they became slightly longer and the peak became slightly less negative with a smaller increase in conductance (Fig. 1A). Summation of HRs was never observed, but they appeared in an all-or-none manner. The repetitive HRs persisted at almost constant intervals for at least 15 min while they were recorded, during which time some additional sperm attached to the egg after the initial rush of sperm. The resting membrane potential shifted gradually in the hyperpolarizing direction to ~ -40 mV, and the conductance increased while the I – V curve remained linear. A small depolarization which appeared immediately after insemination was not induced by sperm, but was caused by serum and/or adrenal gland extract in the sperm incubation medium (Fig. 1Ba, b).

In the conditions used in our experiments, fertilization did not occur in 30% of impaled eggs. Table 1 indicates that the occurrence of HR(s) was associated with sperm entry into an egg

Table 1 Correlation between HR(s) and fertilization

	HR (+)*	HR (–)
Sperm entry (+)*	44 eggs	4†
Sperm entry (–)	3‡	20

Sperm entry was determined by observation of male pronucleus or decondensation of sperm head.

* Occurrence of HR or sperm entry, irrespective of the number.

† Additional sperm attached to the egg after the electrode was removed. It is likely that these sperm entered the egg.

‡ The eggs had been damaged, thus decondensation of the sperm head might be prevented.

and that, conversely, sperm failed to enter eggs that had not shown any HR. When sperm with insufficient pretreatment were used, no HR was induced; these sperm have intact acrosomes and stick to the surface but never fuse with the egg¹⁰.

To correlate the occurrence of HR(s) with the interaction between sperm and egg, the number of sperm reaching an egg was restricted by reducing the concentration (1,000–2,000 sperm per 0.4 ml) and by placing a glass half-ring around the egg as a barrier. The first sperm reached and attached to the egg several minutes after insemination ('at' in Fig. 1). Then, using a micromanipulator, we added another half-ring to form a closed ring. Active flagellar motion decreased fairly suddenly, 10–90 s after the sperm had attached. The sperm then stopped moving completely in 10–15 s, becoming straight ('st' in Fig. 1). Table 2 shows that the first HR began in most cases within 10 s before or after the stop of the first sperm: there was a fairly good correlation between the two events.

In Fig. 1C, only one sperm bound to the egg throughout the experiment (Fig. 2A), and it was incorporated into the egg to form a male pronucleus (Fig. 2B). Three HRs appeared during 11 min after the sperm had stopped moving. In 10 out of 13 eggs penetrated by a single sperm, 2–4 HRs appeared within 2 min after the sperm had stopped. The next HR tended to occur after a pause of several minutes, as in Fig. 1C. Another three eggs behaved differently: one showed a continuous series of small HRs and two showed only one. The recurring HRs were also recorded in a zona-intact egg. In the case of Fig. 1D, four sperm attached and stopped separately from each other, and all were found to be incorporated into the egg. The stops of flagellar motion of additional sperm did not always coincide with the occurrence of a HR. However, multiple sperm entries caused a

Fig. 1 Fertilization potential induced by 16(A), one (C) and four sperm (D). To monitor a change in the membrane conductance, repetitive current pulses were applied through the intracellular electrode by means of a bridge circuit, with a current strength of 0.3 nA in A (bottom trace), and 0.2 , 0.5 , 0.5 and 0.15 nA in Ba to D, respectively. The upper trace shows events which were marked electrically by the observer, and also indicates zero potential: ins, insemination; rush, rush of sperm to attach to the egg surface; 1–4 at and st, attachment and stop of the first to fourth sperm. In B, a small depolarization associated with conductance increase was induced by addition of 20 μ l of sperm incubation medium containing 20% human serum (Ba) or 1% bovine adrenal gland extract (Bb). The incubation medium itself had no effect. The egg was insensitive to the second application of serum (Ba). There was a 3-min interruption in the middle of Bb. Concentrations of major ions in the egg medium were as follows (mM): Na $^+$, 119; K $^+$, 5.9; Ca $^{2+}$, 1.7; Mg $^{2+}$, 1.2; Cl $^-$, 102; HCO $_3^-$, 26 (equilibrated with CO $_2$ at pH 7.4).

Fig. 2 The egg from which the record of Fig. 1C was obtained. **A**, After recording of potentials; **B**, after incubation for 4 h. The egg was pressed with a cover slip in **B** to visualize pronuclei. continuous series of HRs without any long pause. The series of HRs persisted although no more sperm became attached.

We conclude that the fertilization potential in hamster eggs consists of recurring hyperpolarizations. In our experiments, the time of recording the potentials after insemination corresponded to the period from contact between sperm and egg to, at most, the incorporation of the entire sperm head into the egg cytoplasm^{10,11}. The HR first appeared at about the time of the first sperm stop, when sperm and egg are likely to fuse¹⁰. The periodic appearance of HRs thereafter may be a consequence of a pre-existing ability of the egg, because similarly shaped HRs appear at almost constant intervals even without correlation with each sperm-egg fusion, as shown in the case of polyspermy (Fig. 1A, D). Repetitive hyperpolarizing responses each with durations of several to 20 s have been found in fibroblastic L cells^{12,13}, macrophages^{14,15} and sympathetic ganglion cells¹⁶. These HRs are due to an increase in the K permeability^{12,15} caused by an increase in intracellular Ca^{2+} ($[Ca^{2+}]_i$)^{14,16,17}. The HRs in hamster eggs had a reversal potential between -85 and -80 mV (our unpublished results), suggesting an increase in K permeability. The HRs in the above cells occur either spontaneously or by electrical, chemical or mechanical stimulations, whereas those in hamster eggs were induced neither by injecting current up to 5 nA nor by pushing the egg with a glass capillary, but they were induced by sperm about to be incorporated into the egg. It has been shown in sea urchin eggs^{18,19} that one of the early events on fertilization is the release of Ca^{2+} from intracellular stores and the consequent increase in $[Ca^{2+}]_i$ mediates several changes such as the discharge of the cortical granules. The HR in hamster eggs may reflect a cyclic change in $[Ca^{2+}]_i$ during incorporation of the sperm into the egg, although the functional significance is unknown.

In echinoderm and echiuran eggs, the membrane potential shifts to positive values during the early phase of the fertilization potential, due to an increase in membrane permeability to Na^+ and possibly Ca^{2+} (ref. 1). In the medaka fish, *Oryzias latipes*, fertilization triggers a depolarization of a few mV followed by a longer hyperpolarizing phase with an amplitude of ~30 mV, when the resting potential is more negative than -20 mV (ref. 20). In hamster eggs we could not record any depolarization preceding the HR in recording conditions that were able to detect a change in potential of at least 1 mV. This was also the case when the membrane potential was preliminarily shifted to

-64 to -68 mV by applying current. In one of four such cases, the membrane potential and effective resistance were -65 mV and 310 M Ω , respectively. We have proposed an equivalent electrical circuit for the egg plasma membrane²¹ analogous to circuits for subsynaptic membranes of nerve cells²². If one assumes a possible 1-mV depolarization caused by a shunting conductance (g_s) with a reversal potential of -20 mV, the g_s in the above egg is calculated as 72 pS. If the potential is clamped at -65 mV, the g_s causes a membrane current of 3.2 pA. Thus, the depolarizing response, if any, is negligibly small. Furthermore, preliminary experiments indicated that the potential-dependent fertilization block shown in echinoderm^{2,3}, echiuran⁴ and frog⁵ eggs does not exist in the hamster egg. These differences stimulate further experimentation in mammalian eggs.

We thank Drs A. Hanada and Y. Hirao for teaching us the techniques of fertilization *in vitro* and for valuable advice, Dr S. Ozawa for criticism, and Miss Y. Hodota for technical assistance.

Electrical coupling between fibre cells in amphibian and cephalopod lenses

T. J. C. Jacob & G. Duncan

School of Biological Sciences, University of East Anglia, Norwich NR4 7TJ, UK

The lenses of vertebrate and cephalopod eyes differ ontogenetically and in other respects. The vertebrate lens, derived from a single cell type, consists mainly of long fibre cells continuously produced by division and elongation of columnar epithelial cells near the lens equator. Almost 50% of the fibre cell surface consists of junctional complexes^{1,2} and the internal resistance, from point to point within the lens, is low compared with the surface membrane resistance³. Thus the vertebrate lens is expected to behave as a well coupled syncytial system⁴. The cephalopod lens, however, is formed by the fusion of two distinct cell types⁵; the anterior segment has the same ontogenetic origin as the cornea but the posterior segment shares a common origin with the retina, and the plane of contact of the two cell types can be seen in light-microscope sections⁵. Most of the lens is composed of long fibre cells similar in appearance to those found in the vertebrate lens, and membrane junctional regions between adjacent fibres have also been tentatively identified⁶. We now describe electrophysiological investigations of cellular communication in the cephalopod lens, which show marked differences in the intercellular electrical coupling within the vertebrate (amphibian) and cephalopod lens.

Table 2 Timing of the initiation of the first HR in relation to the first sperm 'stop'

Time (s)	Eggs	Time (s)	Eggs
-5-0	11	0-5	10
-10--5	5	5-10	6
-15--10	1	10-15	2
-----15	0	15-20	2
		20----	4

The time when the flagellar motion of the first sperm ceased was taken as zero time.

Fig. 1 Voltage-clamp responses at two positions (V_1 and V_2) within the cortex of the perfused lens of the frog *Rana pipiens* (for dissection and solution details, see ref. 9). The experimental arrangement allowed for two separate voltage-measuring circuits. The first electrode (V_1) measured the lens transmembrane voltage with respect to a reference in the bath and was coupled by a voltage-clamp circuit to the current-injection microelectrode (I) so that the lens could be clamped at any given voltage (see ref. 9 for further details). The voltage was also measured by an independent differential amplifier circuit between a third internal microelectrode (V_2) and a separate reference electrode in the solution flowing round the lens. The upper trace shows 2-mV command pulses superimposed on a resting voltage of -75 mV. The middle trace gives the response of the independent electrode where the resting baseline was -74 mV. V_2 in this case was placed one half of a lens diameter from V_1 . The clamp current (I) consists of a sharp spike, indicating current flow through the large membrane capacitance¹⁰ followed by a decline to a plateau value when current is flowing through the pure resistive components of the lens membranes. The voltage and current responses were found to be independent of the relative positions of the three widely-spaced electrodes.

Insertion of three microelectrodes into the frog lens does not significantly impair its membrane characteristics as stable, high (mean $\pm$ s.e.m. = 77.8 ± 0.7 mV from 29 lenses) resting potentials were obtained during these experiments. The voltage recorded at electrode V_1 was always within 1–2 mV of that recorded at V_2 . When V_1 was clamped at the resting voltage (Fig. 1), V_2 also remained clamped and when a 2-mV pulse (either hyperpolarizing or depolarizing) was superimposed on the resting voltage (V_1), a very similar change in baseline was also recorded at V_2 . The coupling ratio (V_1/V_2) obtained in four such experiments was 0.98 ± 0.1 .

However, the voltage-clamp responses obtained from three similar internal electrode experiments on the perfused lens of the cephalopod *Sepiolo atlantica*, depended on the relative positions of the current and voltage electrodes (Fig. 2). When the current and command voltage electrodes were both placed in the anterior segment and the independent voltage electrode in the posterior, a 2-mV command pulse was not accompanied by a 2-mV response at the posterior electrode (Fig. 2a); the coupling ratio defined by V_p/V_a was in fact only 0.06. These responses were mirrored when the command and current electrodes were

Fig. 2 Voltage-clamp responses at the anterior and posterior segments of the perfused cephalopod lens (for details of dissection methods and solution composition, see ref. 6). The command voltage microelectrode and current injection electrode were always placed in the same segment of the lens and the shape of the voltage and current signals obtained in response to a command pulse of 2 mV were very similar to those obtained from the vertebrate lens (Fig. 1). However, the magnitude and time course of the response measured by the independent voltage circuit depended on whether the command and independent electrode were located in the same lens segment. When they were in different segments (as in a and b), the independent signal was greatly reduced in amplitude and its shape followed that of the clamp current rather than the command voltage. When the two voltage electrodes were in the same segment (as in c), the amplitudes and shapes of the responses were very similar. Note the difference in vertical scale magnitudes of the clamp currents in a and b, which is due to the fact that the resistance of the anterior segment is greater than that of the posterior (Table 1).

both in the posterior segment, with the independent electrode in the anterior (Fig. 2b); the coupling ratio (V_a/V_p in this case) was again 0.06 and the mean value obtained from eight such experiments was 0.072 ± 0.015 . When the three electrodes were placed in the same segment (either anterior or posterior), the command pulse was followed precisely by the independent electrode (Fig. 2c). Hence cells within one segment are closely coupled, but there is little communication between segments.

The resting voltages recorded in the two segments were very similar (Table 1), but the resistances were quite different. However, the surface area of the anterior segment in the *Sepiolo* lens is about half that of the posterior (our unpublished observations), thus when the data are expressed as specific resistance ($k\Omega \text{ cm}^2$) the two values are almost equal. This suggests that although the membranes of the fibre cells in the two segments have a different origin and although they are not coupled, their membrane permeability properties may be quite similar. The specific resistances of the *Sepiolo* segments are both considerably smaller than the specific resistance of the frog lens, which Delamere and Duncan⁶, ascribed to the very high potassium permeability of the *Sepiolo* lens membranes.

Table 1 Accumulated potential and resistance data for the amphibian (*Rana pipiens*) and cephalopod (*Sepiolo atlantica*) lenses

	Potential (mV)	Resistance (k Ω)	Surface area ($\times 10^{-2} \text{ cm}^2$)	Specific resistance (k $\Omega \text{ cm}^2$)
<i>Rana</i> lens	-77.8 ± 0.7 (29)	10.9 ± 0.48	33.9 ± 1.17	3.69 ± 0.144
<i>Sepiolo</i> lens anterior	-62.5 ± 1.4 (15)	6.34 ± 0.49	6.9 ± 0.3	0.44 ± 0.026
posterior	-62.2 ± 2.0 (9)	3.49 ± 0.87	15.3 ± 0.59	0.53 ± 0.07

Data are mean $\pm$ s.e.m. and values in parentheses represent the number of lenses in each case.

The fact that the two segments of the cephalopod lens are not closely coupled (Fig. 2a, b) poses interesting problems for the regulation of growth and raises a further issue concerning the crystallin protein composition of the two halves. As they are of different ontogenetic origin, and because they remain functionally separate throughout development, it is very likely that they are composed of different protein species. Although the proteins of cephalopod lenses have been investigated in some detail⁷ and the nuclear and cortical components seem to be different,⁸ no studies have been made of the two halves separately.

The cephalopod lens thus provides a unique opportunity for comparative evolutionary and developmental studies. Not only has it developed one mechanism in parallel with the vertebrate lens for producing a highly refractile, transparent focusing system (that is, by close-packed array of fibre cells of surface ectodermal origin), but it has also evolved a second and apparently independent mechanism for producing crystallins and fibre cells from a second cell type (vesicular epithelium).

Rhodopsin-like photosensitivity of isolated chicken pineal gland

Takeo Deguchi

Department of Medical Chemistry, Tokyo Metropolitan Institute for Neurosciences, 2–6 Musashidai, Fuchu-city, Tokyo 183, Japan

The pineal gland of lower vertebrates such as fish, amphibians and reptiles is primarily a photoreceptor organ and its electrical activity changes in response to environmental lighting^{1–3}, whereas the mammalian pineal gland is a secretory organ and no longer responds to direct illumination. It is uncertain whether the avian pineal gland retains a photoreceptive capability^{4–8}, and also whether the gland is a photosensor involved in the photo-periodic control of reproductive systems and circadian rhythms in birds^{9–14}. Recently, I and other workers have shown that the circadian rhythm of serotonin *N*-acetyltransferase activity persisted in organ cultures of chicken pineals, indicating the presence of an endogenous circadian oscillator in the gland^{15–19}. Also, the observation that direct illumination of cultured chicken pineals suppressed the night-time increase of *N*-acetyltransferase activity^{16,20} suggests that the gland contains a photoreceptor. I report here that the action spectrum of the photosensitivity of the isolated chicken pineal resembles the absorption spectrum of rhodopsin.

Chickens (White Leghorn cockerels) were maintained in our animal facility with light from 7 a.m. to 7 p.m. for 14–18 days after hatching. The chickens were killed by decapitation at 6 p.m. and five pineals were placed on nylon mesh in a Falcon plastic organ culture dish (no. 3037) containing 1.5 ml of BGJb medium without phenol red. They were cultured as described elsewhere¹⁶ from 7 p.m. to 1 a.m. under a monochromatic and energy-calibrated photic stimulus. As controls, a group of pineals was cultured in darkness (dark control) and another

Table 1 Effect of depolarizing and hyperpolarizing agents on *N*-acetyltransferase rhythm in organ cultures of chicken pineal gland

Addition	<i>N</i> -acetyltransferase (pmol per 10 min per pineal)	
	Light	Dark
None	152 ± 12	997 ± 50
55 mM KCl	434 ± 58	990 ± 131
Nonactin (20 µM)	115 ± 13	107 ± 15
Valinomycin (4 µM)	129 ± 10	135 ± 11
Before culture	98 ± 6	

Pineals were organ-cultured from 7 p.m. to 1 a.m. in darkness or under 70 µW cm⁻² of white light in the presence of the agents indicated. There were five samples in each group and the results are the means ± s.e.m.

group under 70 µW cm⁻² of white light from a xenon arc lamp (light control).

When pineals were cultured from 7 p.m. to 1 a.m. in darkness, *N*-acetyltransferase activity increased from 75–120 to 750–1,300 pmol per 10 min per pineal. When they were cultured under continuous illumination, the enzyme activity increased only to 150–250 pmol per 10 min per pineal. Culture under various intensities of 400, 500, 600 and 700 nm wavelengths (Fig. 1a) showed 500 nm to be the most effective wavelength for inhibiting *N*-acetyltransferase activity. At this wavelength there was a significant decrease of the enzyme activity with an intensity of 0.02 µW cm⁻² ($P < 0.05$), and maximum inhibition with 0.3 µW cm⁻², which was equivalent to that caused by 70 µW cm⁻² of white light. With the wavelength of 400 nm maximum inhibition occurred at 1 µW cm⁻², while 600 nm was far less effective, showing no significant inhibition with 0.3 µW cm⁻² and a submaximum inhibition with 10 µW cm⁻². The wavelength of 700 nm showed no effect on enzyme activity with 7 µW cm⁻² or less. When the reciprocals of the light intensities producing 50% inhibition of the night-time increase of *N*-acetyltransferase activity were plotted as sensitivities on the ordinate in a logarithmic scale (Fig. 1b), the sensitivity curve resembled the absorption spectrum of rhodopsin²¹. On examining the effects of wavelengths from 400 to 800 nm at 0.3 µW cm⁻², maximum inhibition occurred at 500 nm and a submaximum inhibition at other wavelengths (Fig. 2). The most effective wavelengths were 500 and 520 nm, and there was a sharp cutoff of the inhibitory effect at longer wavelengths, with a gradual decrease at shorter wavelengths.

A high enough concentration of KCl (55 mM) to depolarize the cell membrane partially restored the light-induced suppression, but did not enhance the dark-time increase of *N*-acetyltransferase activity (Table 1). On the other hand, the dark-time increase of *N*-acetyltransferase activity was completely inhibited by potassium ionophores (nonactin or valinomycin), which hyperpolarize the cell membrane. I have previously shown that cocaine, which prevents depolarization of neural cells, and catecholamines, which induce hyperpolarization in the rat pinealocyte, block the night-time elevation of *N*-acetyltransferase activity²².

The threshold light intensity of the chicken pineal is in the range of the threshold intensities of several photosensitive systems²³. As dispersed cells responded to a photic stimulation in the same manner as organ culture²⁴, it seems reasonable to speculate that a rhodopsin-like photosensitive substance is incorporated in the cell membrane of pinealocytes. Electron microscopic studies of avian pineals revealed cells with whorls of lamellae and a modified structure, which some investigators consider photosensory^{6,7} but others believe to be abortive or vestigial photoreceptor cells⁸. Such a structure might participate in the regulation of *N*-acetyltransferase activity.

It is firmly established that the membrane potential of retinal photoreceptor cells of vertebrates and of frog pineals are depolarized in darkness and hyperpolarized by photic stimulation^{3,25}. It is therefore conceivable that direct illumination of the

Fig. 1 Effect of various intensities of monochromatic light on the night-time increase of *N*-acetyltransferase activity in organ cultures of chicken pineal. A monochromatic stimulator (model TD-3, Sanso Seisaku) with a xenon arc lamp (XW-500, 500 W) was used. White light from the xenon lamp was divided into three channels and the light energy was calibrated by using an optical wedge and neutral density filter. Monochromatic light was obtained by interference filters (half width <11 nm) and the beam was transmitted into a CO₂ incubator through a quartz window. The stimulating light was reflected downwards with a mirror and projected on to a culture dish. The intensity of light was measured at the level of the dish by use of a radiometer (model 470D, Sanso Seisaku) and expressed as $\mu\text{W cm}^{-2}$. *a*, Pineals were cultured from 7 p.m. to 1 a.m. under the intensities of monochromatic light indicated. *N*-acetyltransferase activity is shown as per cent of dark control, which was run in each experiment. Points and bars show means and s.e.m. of values of five samples. *b*, Reciprocals of the intensities that produced 50% inhibition are plotted as sensitivities on the ordinate in a logarithmic scale.

chicken pineal produces a slow, long-lasting hyperpolarization of the pinealocyte membrane and prevents the nocturnal increase of *N*-acetyltransferase activity. Such speculation is supported by the present finding that depolarizing agents restored the light-suppression of *N*-acetyltransferase activity and hyperpolarizing agents prevented the night-time increase of the enzyme activity.

Kato *et al.* reported that red, but not green, radioluminous paint applied to the skin above the pineal gland of Japanese quail promoted testicular development¹⁴. Woodard *et al.* also showed that in Japanese quail red light accelerated sexual maturity more effectively than green light²⁶. In contrast, Menaker showed that green light (0.1 lx) was effective in entraining the circadian rhythm of perching activity in blinded sparrows²⁷. In my study, green light was most effective in inhibiting the *N*-acetyltransferase rhythm. The discrepancy between these observations is unclear. However, in the present study pineals were directly illuminated, whereas in other studies animals were placed under a specified wavelength of light. It is possible that shorter wavelengths were absorbed by skin, skull, blood and other tissues before reaching the pineals. Alternatively, the hypothalamic, but not pineal, photoreceptor may sense longer wavelengths of light, thus affecting photoreproductive function in living birds.

Menaker and his associates have demonstrated that in house sparrows the pineal gland functions as a biological clock that

controls the circadian rhythms of locomotor activity and body temperature²⁸. The gland presumably regulates such functions by secretion of melatonin, a pineal hormone^{29,30}. The activity of serotonin *N*-acetyltransferase, the key enzyme in the synthesis of melatonin³¹⁻³³, shows a circadian rhythm and responds to direct illumination in the isolated chicken pineal glands, as reported here. Recently, Takahashi *et al.*³⁴ have shown that the synthesis and release of melatonin from cultured chicken pineal glands also exhibit a circadian change and respond to environmental lighting, suggesting that the light perception of the avian pineal gland, by affecting the synthesis of melatonin, has a physiological role in the regulation of functions and behaviour in birds.

Fig. 2 Effect of various wavelengths on the *N*-acetyltransferase activity in organ culture. Pineals were cultured from 7 p.m. to 1 a.m. under an intensity of $0.3 \mu\text{W cm}^{-2}$ of the monochromatic light indicated. The results are shown as per cent of dark control. Points and bars indicate means and s.e.m. of five samples.

Functionally significant central-pair rotation in a primitive eukaryotic flagellum

Charlotte K. Omoto*† & George B. Witman*

There is now considerable evidence that the basis for ciliary and flagellar movement is an active sliding between peripheral doublet microtubules which, when resisted by structures within the axoneme, leads to axonemal bend formation¹⁻⁴. In contrast, relatively little is known about the control mechanisms which coordinate the interdoublet sliding and axonemal bending to produce the effective motion observed in various cilia and flagella⁵. One component of the axoneme which may be involved in this control is the central pair of microtubules^{6,7}. To learn more about the action of the central pair, we have studied the tiny uniflagellate marine alga, *Micromonas pusilla*. The central tubules of the *M. pusilla* flagellum extend for several micrometres beyond the termination of the peripheral doublets⁸, thus permitting direct observation of the central pair during flagellar movement. Our findings, reported here, indicate that in living *M. pusilla* the central pair of microtubules undergoes continuous rotation in one direction. This rotation provides the motive force for the cell.

Our observations on the ultrastructure of the flagellum of *M. pusilla* (previously named *Chromulina pusilla*⁹) agree well with those of Manton⁸. The flagellum is ~5 µm long and has the appearance of a short thick stub terminated by a long thin fibre (Fig. 1a). The thicker proximal portion is about 0.2 µm in diameter and contains the normal '9+2' array of microtubules, but is less than 1 µm long (Fig. 1e). The thinner distal portion is ~70 nm in diameter and contains only the central pair of microtubules (Fig. 1b), which are ~5 µm in length and extend for ~4 µm beyond the termination of the peripheral doublets. For most of this distal portion, the flagellar membrane closely surrounds the central pair. Figure 1b and c show the region of transition between the '9+2' flagellum and the thin '0+2' portion containing only the central tubules. At their proximal end, the central tubules terminate just above the basal body (Fig. 1f), as in other cilia and flagella^{10,11}.

The flagella of living *M. pusilla* can be observed by dark-field light microscopy. In free-swimming cells, the distal '0+2' portion takes on a helical configuration and seems to rotate, pushing the cells through the medium like a propeller. This portion of the flagellum also appears to rotate in cells which are stuck to the glass slide by their cell bodies (Fig. 2). The short '9+2' region is usually obscured by glare from the cell body, but in fortuitous views it is seen to wave back and forth, as would be expected for a very short flagellum undergoing a normal beat cycle. The '0+2' portion of a non-moving flagellum retains its helical configuration. By focusing through such a flagellum, we determined that the helix is left-handed.

One cannot be sure from the above observations alone that the movement of the '0+2' portion of the flagellum is due to actual rotation as opposed to propagation of helical waves along a non-rotating flagellum. However, these two possibilities can be distinguished by anchoring the cell to the glass slide by its flagellum and observing the resulting motion of the cell body. When *M. pusilla* are placed on silicone-coated slides, many cells stick to the slide by one end of the cell body and spin rapidly around the point of attachment, as previously described by Manton and Parke⁹. However, some cells stick to the slide by the flagellum; when this occurs, the cell body rotates (Figs 3, 4). In

Fig. 3, the rotational axis is almost perpendicular to the slide, so that the rotation looks like that of a wheel viewed from the side. In Fig. 4, the rotational axis is nearly parallel to the glass slide and rotation is inferred by the changes seen in the shape and the markings of the cell. The position and curvature of the flagellum of this cell remain constant throughout the 360° rotation of the cell body, indicating that the flagellum is stuck to the slide and immobilized over most of its length. In all such cells so far observed, the cell bodies were rotating clockwise as viewed from the flagellum. This would correspond to an anticlockwise rotation of the '0+2' portion, looking from tip to base. These observations indicate that the distal portion of the *M. pusilla* flagellum, and by inference, the pair of central tubules therein,

Fig. 1 Structure of *M. pusilla* flagellum. *a*, Electron micrograph of a negatively stained *M. pusilla*. The distal portion of the flagellum beyond the arrow is about 70 nm in diameter and is too thin to contain the usual '9+2' axoneme. The dotted lines and brackets labelled *b-f* indicate the approximate levels of the corresponding cross-sections. *M. pusilla* was grown under continuous light on Ergschieber's medium²⁰. A drop of the cell culture was placed on a Formvar-coated grid and stained with 2% uranyl acetate. $\times 15,275$. *b*, Cross-section through distal portion of the flagellum where only the central tubules remain. Note that the membrane closely surrounds the two tubules, which seem to be closer to each other than in the usual '9+2' structure. *c*, Cross-section through the flagellum just distal to the point where the peripheral tubules have terminated. *d*, Cross-section where some of the peripheral tubules have terminated. *e*, Cross-section through the proximal portion of the flagellum, showing the typical '9+2' axoneme. *f*, Cross-section at the base of the flagellum, showing the axosome just proximal to the origin of the central tubules. *b-f*, $\times 83,800$. *M. pusilla* was 'instantaneously fixed'¹² in glutaraldehyde- OsO_4 , embedded in agar, then dehydrated and embedded in Spurr's plastic²¹. Sections were stained with uranyl acetate and Reynold's lead citrate²².

Fig. 2 Sequence from 16-mm cine film of *M. pusilla*. The cell is stuck to the slide and the flagellum seems to rotate. Most of the flagellum seen is the '0+2' region, the '9+2' region being too short to be visible much beyond the glare of the cell body. Dark-field optics⁶; consecutive frames progress from left to right. 64 frames per s. $\times 2,000$.

rotates. The evidence does not rule out the possibility that the whole flagellum, including the '9+2' region, rotates, but this seems highly unlikely.

The anticlockwise rotation together with the left-handed twist of the flagellum are consistent with the observed progression of the cell through the medium, with the flagellum pushing the cell. Interestingly, the direction of central-pair rotation in *M. pusilla* is the same as that reported for the central pair in *Paramecium*^{7,12}.

The membrane which surrounds the central microtubules probably rotates with the central pair; this is especially evident in a rotating cell which is anchored to the slide by its flagellum, but even in free-swimming cells connections between the central pair and the membrane might cause the membrane to move with the underlying tubules. Such a movement would result in a shear zone in the flagellar membrane at some point along the flagellum, probably at the base of the '0+2' portion. We have observed no discontinuity in the cell or flagellar membrane of *M. pusilla*, so the surface shear must be readily absorbed by the fluid membrane. A similar situation occurs in the plasma membrane of some devescovinid flagellates, where one portion of the cell

surface continuously rotates relative to the rest of the cell surface¹³.

We do not know what causes the central pair to rotate. One possibility is that the rotation is a passive response to three-dimensional bending of the '9+2' portion of the flagellum. Alternatively, rotation may be the result of interactions between the radial spokes and the central sheath in the '9+2' region, or might be caused by a rotary motor in the axosome where the central tubules originate. Further studies will be necessary to determine the basis for the rotation.

Central-pair rotation has now been demonstrated for *M. pusilla* flagella, and implicated in *Paramecium* cilia^{7,12}, *Opalina* cilia¹⁴ and *Synura* flagella¹⁵. Central-pair rotation may therefore occur in the cilia and flagella of many organisms. In *M. pusilla*, rotation of the central pair propels the cell through its medium. The function of central-pair rotation in the normal '9+2' axoneme is unknown, but several observations suggest that the central microtubules are involved in the control of ciliary and flagellar movement. Flagella lacking the central tubules are paralysed, although the ability of the dynein arms to cause sliding is apparently normal¹⁶. The central tubule-central

Fig. 3 Film sequence showing a cell stuck by its flagellum (visible in the original cine film) to a silicone-coated slide and the cell body rotating. The slide was coated with silicone by wiping it with silicone-treated lens paper (Sight Savers, Dow-Corning). The sequence was printed to enhance the visibility of the dark spot (white arrowheads) on the cell body. The cell-body rotation can be followed using the dark spot as a marker. The cell is rotating anticlockwise. Consecutive frames run from left to right beginning in the upper left-hand corner. Dark-field optics, 64 frames per s. $\times 2,880$.

Fig. 4 Top row: dark-field light micrographs of *M. pusilla*. The cell is attached to a silicone-coated slide by its flagellum and the asymmetric cell body is rotating. Recorded on continuously moving film with stroboscopic illumination at 60 Hz. $\times 3,200$. Second row: photos of a styrofoam and wire model. The wire, representing the '0 + 2' portion, is held in place and the angle of insertion of the wire and the cell body orientation are changed and photographed. The numbers below each image indicate the angle of insertion relative to the cell surface, and the angle through which the cell body has rotated relative to the surface to which the flagellum is attached, respectively.

sheath complex is asymmetrical in several organisms, and this asymmetry may be related to the formation of asymmetrical axonemal bends^{6,16}. The orientation within the axoneme of the central pair of microtubules is correlated to beat direction in a variety of cilia and flagella^{14,17,18}; moreover, the orientation of the central pair has been reported to change along the length of the axoneme^{12,19}, with change in beat direction¹⁴, and during the beat cycle^{7,12,15}. Thus, it has been proposed that the central microtubules undergo a systematic movement correlated with the beat cycle and that this movement is involved in regulating the motion of the axoneme, possibly by determining which doublets undergo active sliding at any particular phase in the beat cycle⁷. Regulation of dynein arm activity around the axoneme would be particularly important in cilia and flagella having a three-dimensional waveform.

The cultures of *M. pusilla* were provided by the Culture Centre of Algae and Protozoa (Cambridge, UK) and the Culture Collection of Algae (University of Texas, Austin). We thank Jana Olson Kiefer for providing the growth medium, Nick Minervini for assistance with photography and electron microscopy, Gary Gorbysky for his suggestion of using 'Sight Savers' for coating slides and Drs Ching Kung, Howard Berg and Charles J. Brokaw for helpful criticism and encouragement. Figure 4 was made possible by the invaluable assistance of Dr Brokaw at the California Institute of Technology, Kerckhoff Marine Laboratory. This work was supported in part by NIH grants GM 21586 to G.B.W., GM 07445 to C.K.O. and GM 18711 to C.J.B.

Two phospholipase pools for prostaglandin synthesis in macrophages

Wei Hsueh, Usha Desai, F. Gonzalez-Crussi, Ruth Lamb & Agnes Chu

The Department of Pathology of The Children's Memorial Hospital, Northwestern University Medical School, Chicago, Illinois 60614, USA
The Department of Pathology of University of Connecticut Health Center, Farmington, Connecticut 06032, USA

Macrophages in culture produce prostaglandins in response to a variety of phagocytic and non-phagocytic stimuli¹⁻⁸. As prostaglandins are not stored in cells, and mammalian cells contain very little free arachidonic acid, synthesis and release of prostaglandins depends on the release of the precursor, arachidonic acid, from cell lipids. Many agents that stimulate cell prostaglandin production act by releasing arachidonic acid⁹, presumably by activating phospholipase A₂ (refs 10, 11) or phospholipase C (refs 12, 13), depending on the cell system used. We have shown previously that rabbit alveolar macrophages secrete arachidonic acid as well as prostaglandins in response to phagocytic stimuli^{2,4,6}. This secretion depends not on particle attachment, but rather on interiorization of the particles⁴. Furthermore, the time course of prostaglandin and arachidonic acid secretion does not parallel that of particle engulfment *per se*, but of the release of lysosomal enzymes⁴, indicating that the release of arachidonate and prostaglandin is associated with the latter. We now describe experiments which suggest that these are two independent pools of phospholipases in macrophages, one in the lysosomes and one elsewhere.

To assess the prostaglandin release, we prelabelled the cell lipids of cultured rabbit alveolar macrophages (more than 90% macrophages) with ^{14}C -arachidonic acid (Amersham) as previously described². Analysis of the cell lipids showed a pattern of incorporation similar to that of our previous studies²: approximately 40–50% of the radioactive arachidonic acid was incorporated into cell lipids after 1 h of incubation. Most of the radioactivity (75%) was found in phospholipids, particularly in phosphatidylcholine ($48 \pm 1\%$, $n = 10$) and phosphatidylethanolamine ($19 \pm 1\%$). A small amount also resided in phosphatidylserine and phosphatidylinositol ($8 \pm 1\%$) and neutral lipids ($5 \pm 1\%$). Less than 2% of the radioactivity in cells remained in the free fatty acid fraction.

Stimulation of macrophages with various phagocytic and non-phagocytic stimuli resulted in prostaglandin release. However, only a small amount of arachidonic acid could be detected in the medium in the absence of serum. This is probably due to immediate reincorporation of the unreacted arachidonic acid into phospholipids. To avoid this problem, we used fatty acid-free bovine serum albumin to 'trap' the released fatty acid^{2,14}. Thus, the activity of phospholipase could be quantitatively assessed.

We have previously demonstrated a close association between the release of lysosomal enzyme and that of arachidonic acid and prostaglandin by macrophages, following zymosan phagocytosis^{2,4}. This suggests a cause-effect relationship between these two mechanisms. Prostaglandin synthesis, however, does not regulate lysosomal enzyme release, as inhibition of the former did not affect the latter^{2,15}. As alveolar macrophage lysosomal granules do contain phospholipase A₂ (ref. 16), it is possible that phagosome-lysosome fusion, on releasing acid hydrolases, activates lysosomal phospholipase, thus explaining the close

association between release of arachidonic acid and lysosomal enzyme. To investigate further whether activation of lysosomal enzyme *per se* is sufficient to elicit prostaglandin synthesis, we examined the effect of C5 fragment, a chemotactic agent known to elicit lysosomal enzyme release¹⁷, on arachidonic acid release and prostaglandin synthesis. The effect of C5 fragment was then compared with that of zymosan phagocytosis. As shown in Fig. 1b, both zymosan and C5 fragment resulted in significant increased release of arachidonic acid, up to 4–5 times the control. However, these two agents produced different effects on the coupling efficiency of phospholipase (arachidonic acid release) and cyclooxygenase (prostaglandin synthesis). Figure 1a shows that prostaglandin synthesis was increased to 2.5 times the control value following zymosan stimulation, but only to 1.1 times control value after C5 fragment treatment. Thus, phagocytosis of zymosan resulted in tight coupling between arachidonic acid release and prostaglandin synthesis (arachidonate/prostaglandin ratio = 3, Fig. 1d), whereas C5 fragment, with an arachidonate/prostaglandin ratio of 7.7 (Fig. 1d), produced a disproportionately small prostaglandin synthesis for a large arachidonic acid release. Lysosomal enzyme release remained comparable with both stimulants (approximately three times the control value, Fig. 1c).

Because it is generally accepted that phospholipase, not cyclooxygenase, is the rate-limiting enzyme for prostaglandin synthesis, this dissociation between arachidonic acid release and prostaglandin synthesis by C5 fragment can only be explained as

Fig. 1 Release of ^{14}C -prostaglandin, ^{14}C -arachidonic acid and acid phosphatase by rabbit alveolar macrophages in response to different stimuli. Rabbit alveolar macrophages were collected by lung lavage and plated in Dulbecco's modified Eagle's medium (DMEM) containing 15% fetal calf serum as previously described² (5×10^6 cells per ml per plate). After overnight incubation, the cells were changed to serum-free DMEM. ^{14}C -arachidonic acid (specific activity 55 mCi mmol^{-1} , Amersham) was added to the cultures as the sodium salt at a concentration of $1 \times 10^6 \text{ c.p.m. ml}^{-1}$. The cultures were incubated for 1 h to label the cell lipids. The cells were washed twice with DMEM and changed to DMEM containing 2 mg ml^{-1} fatty acid-free bovine serum albumin. Different stimuli with or without indomethacin were added to the cells and were incubated for 2 h. At the end of incubation, the medium was collected, an aliquot (1/10) was saved for acid phosphatase determination by fluorometric methods as described earlier. The remainder was acidified to pH 3.5, extracted with ethyl acetate and applied to silica gel G plates². The solvent system used for separation of prostaglandins and arachidonic acid was the organic phase from ethyl acetate/water/iso-octane/acetic acid, 110:100:50:20 (ref. 25). Zones corresponding to various prostaglandin standards and 12-HETE (prepared according to Goetzl *et al.*²⁶) were scraped and counted in a liquid scintillation counter. Total prostaglandin release (sum of 6-keto $\text{PGF}_{1\alpha} + \text{PGF}_{2\alpha} + \text{PGE}_2 + \text{PGD}_2$, c.p.m.) was calculated (a), the zone corresponding to arachidonic acid standard was also scraped and counted (b) and the acid phosphatase activity in the medium was assayed (c). All values are expressed as percentage of unstimulated control. The intracellular acid phosphatase content of the macrophages treated by various stimuli was determined, and found to be the same as that of unstimulated cells (after correction was made for released amount). d, Ratio of release of arachidonase and prostaglandin. The chemotactic fragment of human C5 (C5 fragment) was isolated from human serum and assayed by a modification of Boyden chamber assay as described previously²⁷. The chemotactic activity was expressed in units of ED_{50} . One ED_{50} of chemotaxis is defined as the amount of C5 fragment required for half-maximal chemotactic response in Boyden chamber assay. Z, zymosan (1 mg ml^{-1}); I, indomethacin ($5 \mu\text{g ml}^{-1}$); C5_{fr}, C5 fragment ($75 \text{ ED}_{50} \text{ ml}^{-1}$); PMA, 10^{-6} M . The numbers within the circles give the numbers of experiments. All values are mean $\pm$ s.e.m.

Table 1 Release of arachidonic acid and prostaglandins by alveolar macrophages in response to various stimuli

	Prostaglandins		Arachidonic acid	
	c.p.m.	% Of control	c.p.m.	% Of control
Unstimulated control (<i>n</i> = 9)	750 ± 93	100	898 ± 109	100
Zymosan (1 mg ml ⁻¹) (<i>n</i> = 9)	2,276 ± 283	301 ± 30	9,998 ± 1,326	994 ± 148
PMA (10 ⁻⁶ M) (<i>n</i> = 9)	2,079 ± 294	254 ± 28	7,542 ± 891	736 ± 55
C5 fragment (75 ED ₅₀) (<i>n</i> = 7)	1,008 ± 180	137 ± 21	6,613 ± 909	575 ± 62
Zymosan + PMA (<i>n</i> = 7)	2,942 ± 366	327 ± 45	24,466 ± 3,071	2,681 ± 371
Zymosan + C5 fragment (<i>n</i> = 4)	1,989 ± 265	278 ± 34	10,374 ± 2,059	967 ± 85
C5 fragment + PMA (<i>n</i> = 3)	2,271 ± 618	307 ± 25	38,489 ± 3,152	2,946 ± 384

Prostaglandin (PG) values are the sum of 6-keto PGF_{1α} + PGF_{2α} + PGE₂ + PGD₂(c.p.m.). For methods, see Fig. 1 legend. *n*, Number of experiments, each experiment in duplicate.

follows: (1) there is a switch of arachidonic acid metabolism to the lipoxygenase pathway, (2) C5 fragment inhibits cyclooxygenase, or (3) coupling of phospholipase and cyclooxygenase is prevented, as might occur when a physical distance is interposed between the two enzyme systems within the cell. We can easily rule out (1) as the production of 12-hydroxy-5,8,10,14-eicosatetraenoic acid (12-HETE) and 11-HETE (both comigrate in solvent system used in this study) by macrophages after C5 fragment stimulation is also very low (120 ± 9% of control compared with 247 ± 31% of control after zymosan stimulation, *n* = 5, mean ± s.e.m.). We cannot entirely rule out the second possibility, as C5 fragment slightly inhibited prostaglandin synthesis when added to zymosan-treated macrophages (Table 1). However, this inhibition is minimal, and cannot account for the discrepancy between arachidonic acid release and prostaglandin synthesis following C5 fragment stimulation. We consider the third explanation a more probable one. Cyclooxygenase activity usually resides in the microsomes, probably in the endoplasmic reticulum^{18,19}. Thus, activation of lysosomal phospholipase by C5 fragment resulted in release of arachidonic acid which remained inaccessible to cyclooxygenase. The phenomena implicated in phagocytosis are different. Zymosan engulfment leads to formation of phagosomes and many intracellular vacuoles²⁰, both of which contain plasma membrane and endoplasmic reticulum, on which cyclooxygenase presumably resides. Fusion of lysosomes with phagosomes and these vacuoles may be expected to result in approximation of activated phospholipase and cyclooxygenase. A consequence of this is more efficient coupling between these two enzyme systems.

Phorbol-myristate acetate (PMA), a membrane perturbant, stimulates the production of prostaglandins in MDCK cells²¹ and fibroblasts²². In rabbit alveolar macrophages, PMA, at the concentration of 10⁻⁶M (non-toxic to cells), resulted in high arachidonate and PG release (5- and 2.5-fold control value, respectively) and a very low lysosomal enzyme release (1.3 times control) (Fig. 1*a-d*), suggesting the existence of a phospholipase pool independent of lysosomes. Again, the large amount of prostaglandin synthesis is not due to decrease in lipoxygenase pathway, as the production of 11-HETE and 12-HETE is also very high (230 ± 16% of control, *n* = 5, mean ± s.e.m.). Morphological examination of these cells showed numerous

intracellular vacuoles produced by this chemical at a concentration range of 10⁻⁷–10⁻⁶M (Fig. 2*a*). Both prostaglandin release and vacuole formation became very reduced when the concentration of PMA was reduced to 10⁻⁸M (unpublished data). This observation suggests a close association between vacuole formation and prostaglandin production (Fig. 2*a*). We propose that: (1) the activated phospholipase resides outside the lysosomes, probably on the plasma membrane; (2) activation takes place during vacuole formation; and (3) the released arachidonic acid is immediately acted on by cyclooxygenase and lipoxygenase at the same site. Such a mechanism correlates with the observed efficient coupling between release of arachidonic acid and release of prostaglandin and HETEs. The small amount of lysosomal enzyme release could be due to fusion of lysosomes with the many cytoplasmic vacuoles. The association of vacuole formation and prostaglandin synthesis in mouse peritoneal macrophages stimulated by 12-O-tetradecanoylphorbol-13-acetate has been reported²⁰ as has the tight coupling of phospholipase and cyclooxygenase following stimulation by phorbol diester and other tumour promoters in cultured canine kidney cells^{23,24}. C5 fragment-treated cells are shown in Fig. 2*b* for comparison.

The existence of two pools of phospholipase is further supported by the additive effects of zymosan and PMA and of PMA and C5 fragment (Table 1). A combination of PMA (presumably activating membrane phospholipase) with either C5 fragment (presumably activating lysosomal phospholipase) or zymosan (presumably activating lysosomal phospholipase mainly) resulted in supramaximal increase of arachidonic acid release (26.8 times or 29.4 times the control). In contrast,

Fig. 2 PMA-treated macrophages (*a*) show numerous intracytoplasmic vacuoles. In contrast, C5 fragment-treated cells (*b*) show many cellular processes but less vacuole formation. The cells were fixed in 3% glutaraldehyde and embedded in epoxy resin. Sections (1 μm) were stained with toluidine blue.

Fig. 3 Time course of arachidonic release by macrophages following various stimuli. At time zero, cells were stimulated with PMA (10^{-6} M). Solid line represents time course of arachidonic acid release following addition of PMA at time zero. Note flattening of the curve after 2 h of incubation. The shape of the curve was not altered despite a new dose of PMA (10^{-6} M) at 2 h (— · —). However, addition of zymosan (Z, 1 mg ml^{-1}) at this time caused a sharp increase of arachidonic acid release (— · — · —). All values are mean $\pm$ s.e.m., $n = 3$.

addition of zymosan with C5 fragment did not cause much more increase in arachidonic acid production than with zymosan alone. Note also that prostaglandin synthesis following combined zymosan and PMA treatment was only mildly elevated compared with either stimulus alone (Table 1). A possible explanation is saturation of cyclooxygenase, as both PMA and zymosan were used at near maximal dose in this experiment.

Our hypothesis may also be reconciled with the data illustrated in Fig. 3. Repeated stimulation of macrophages with PMA resulted in flattening of the arachidonate releasing curve, suggesting exhaustion of the non-lysosomal phospholipase pool. Addition of zymosan at this time elicited a second sharp increase of arachidonic acid release, indicating the activation of a different pool of phospholipases, namely the lysosomal phospholipases.

This work was supported by NIH grant 1 R23 AI 16147 and a grant from the American Lung Association. Dr John Pike (Upjohn) provided the prostaglandin standards.

Antigenic structure of influenza virus haemagglutinin defined by hybridoma antibodies

Walter Gerhard, Jonathan Yewdell & Mark E. Frankel

The Wistar Institute of Anatomy and Biology, Philadelphia, Pennsylvania 19104, USA

Robert Webster

St Jude Children's Research Hospital, Memphis, Tennessee 38101, USA

The recurrence of influenza virus infection in man is attributed primarily to changes occurring in the antigenic structure of the viral surface glycoproteins, especially of the haemagglutinin (HA) molecule^{1–4}. Comparative antigenic analysis⁵ of epidemic influenza virus strains has allowed the description of 'strain-specific' and 'cross-reactive' antigenic determinants^{6–8}. However, the interpretation of these findings remained ambiguous, because the specificity of the applied antisera was insufficiently defined and because the antigenic differences among the HA molecules of various epidemic virus strains resulted presumably from a large number of amino acid substitutions^{9–11}. Thus, in characterizing the antigenic structure of the HA molecule, our approach has been (1) to generate a panel of monoclonal anti-HA hybridoma antibodies, (2) to use some of these antibodies to select mutants of the influenza A/PR/8/34 (PR8) virus expressing antigenically altered HA molecules, and (3) to construct an operational antigenic map of the HA molecule by comparative antigenic analysis of the mutant viruses with the monoclonal antibodies. As we report here, analysis of the 34 mutant viruses selected has enabled us to define four antigenic sites on the HA molecule. Our observation that these sites have undergone antigenic drift to a different extent in nature implies that the mechanisms responsible for antigenic drift act selectively on distinct structures of the HA molecule.

Fifty-eight anti-HA hybridoma antibodies were produced by fusion of lymphocytes from spleen and/or mediastinal lymph nodes of 12 BALB/c mice after intraperitoneal or intranasal inoculation with influenza virus¹². PR8 virus mutants with antigenic alterations (each resulting probably from a single point mutation¹³) in the HA molecule were then obtained by incubating cloned PR8 virus seed with selected hybridoma antibodies and by growing the non-neutralized virus fraction in embryonated hen eggs or in the allantois on shell culture system^{14,15}. Antigenic analysis performed by radioimmunoassay (RIA)¹⁶ on each set of mutant viruses (exemplified in Table 1 with mutants (CV) selected with antibody Sa-1) clearly showed that the non-neutralized viruses are antigenic mutants exhibiting an alteration in the HA molecule which reduced the capacity of the selecting antibody (in present example Sa-1) to bind to the mutant viruses in the RIA. Several antigenically distinct mutant viruses were usually selected by any given hybridoma antibody. For example, antibodies Sa-8 and Sa-9 show that mutants CV2 and CV1 are antigenically unique, whereas antibody Sa-14 shows that CV5 differs from CV6. As no monoclonal antibody

Table 1 Antigenic analysis of the mutant viruses selected in the presence of antibody Sa-1

Hybridoma antibody	Amount of antibody (log 2) binding in RIA to PR8 and its mutants				
	PR8-Mt.S. (parental)	CV1	CV2 (CV9)	CV5	CV6 (CV7, CV8, CV10)
Sa-1 (C)	=6.64	<1	<1	<1	<1
Sa-8	=6.64	6.46 ± 0.24	1	6.26 ± 0.45	6.58 ± 0.18
Sa-14	=6.64	<1	2.48 ± 0.98	<1	6.35 ± 0.02
Sa-9	=6.64	2.09 ± 0.94	6.58 ± 0.31	5.71 ± 0.25	5.78 ± 0.65
36 antibodies	=6.64	6.41 ± 0.24	6.36 ± 0.20	6.40 ± 0.13	6.54 ± 0.12

PR8 mutants were selected by titration of PR8-Mt.S. virus seed in the presence of anti-HA hybridoma ascitic fluid in the allantoic cavity of 10-day-old embryonated hen eggs¹⁴ or in the allantois on shell culture system¹⁵. Virus grown at the titration end point was collected and recloned twice in the absence of antibody in embryonated hen eggs. The cloned viruses were grown up to large quantity, purified and quantitated by HA titration. Viral immunoadsorbents were prepared as follows: 250 µl of HAS (phosphate-buffered saline, 0.04% sodium azide) containing 8×10^4 haemagglutinating units (HAU) of purified virus was mixed with 250 µl of HAS containing 2% NP40, incubated for 30 min at 37 °C and then diluted 1:10 with HAS. These viral NP40 stock solutions could be stored at 4 °C without detectably losing their antibody-binding capacity. The viral immunoadsorbents were prepared by incubating wells of polyvinyl microtitre plates overnight at room temperature with 25-µl aliquots of 1:100 dilutions of the viral NP40 stock solutions (corresponding to 4 HAU of undisrupted virus per well). The plates were incubated for 1 h with HAS containing 1% bovine serum albumin before use in RIA. Supernatants from hybridoma cultures were titrated in the RIA in serial 1:2 dilution steps against the parental viral immunoadsorbent. A standard binding curve was generated in this way for each antibody. One dilution of each antibody (upper part of approximately linear range of the standard curve) was then tested in the RIA against parental and the mutant viral immunoadsorbents. The c.p.m. observed in the parental interaction were defined as 100% (log 2 = 6.64). The antibody-mutant interactions were then expressed as a fraction (log 2) of the standard binding curve of the antibody-parental virus interaction. In each assay a given antibody was tested in parallel on the parental virus (quadruplicate samples) and on the individual mutants (duplicates) of a mutant set. Each assay was performed at least three times. The data in Table 1 are expressed as the mean ± standard deviation of three or four assays. The average standard deviation of antibody-mutant binding values (in the binding range of 4.64–6.64) is 0.37. This value was computed from 35 individual antibody-mutant interactions that were repeated independently of each other over ~1 yr.

was able to discriminate between either CV2 and CV9 or between CV6, CV7, CV8 and CV10, it is possible that the mutant viruses within each of these groups exhibit the same mutation. Lastly, the finding that 36 of the 58 anti-HA antibodies reacted equally well with parental virus and any of the C variants indicates that the antigenic changes induced by individual mutations represent minor modifications in a largely conserved antigenic background.

The observation that individual mutations concomitantly modify certain epitopes¹⁷ (structure on the antigen directly complementary to the combining site of a given antibody) provides an operational basis for the construction of an epitope map^{18,19}. Thus, in the example given above, a relationship between the epitopes delineated by antibodies Sa-1, Sa-8, Sa-9 and Sa-14 is clearly shown by the observation that these epitopes were changed by one or several of the mutations exhibited by the CV mutant viruses. This approach for mapping the antigenic structure of the HA molecule is limited, however, by the number and types of distinct antigenic mutants available for comparative analyses. Thus, the epitopes delineated by the 36 hybridoma antibodies which reacted equally well with the parental virus and the CV mutants could not be mapped on the basis of the CV-mutant virus analysis. We have proceeded, therefore, to select from the same cloned PR8 virus seed additional mutants in the presence of 10 other monoclonal anti-HA antibodies. Each set of mutants was then subjected to an antigenic analysis as exemplified in Table 1 with the CV mutants. A total of 75 PR8 mutants were analysed, of which 34 exhibited a unique antigenic modification. The other 41 mutants could not be further differentiated from a corresponding unique mutant by the present antibody panel and thus probably represent multiple isolates of those unique mutants.

The composite results of the comparative antigenic analyses of the mutants are shown schematically in Fig. 1 where each row represents the reactivity of an anti-HA antibody in RIA with the parental virus (column 1) and the 34 antigenically unique mutants (columns 2–35). Three antibody-binding values are distinguished, black, cross-hatched and white squares representing >50, 25–50 and <25% of the binding to parental virus, respectively. All the hybridoma antibodies, except antibodies Cx-1 to Cx-8, exhibit reduced binding to one or several of the virus mutants. Antibodies and mutant viruses could thus be assembled into four complementary antibody-virus mutant groups designated Sa, Sb, Ca and Cb (the choice for the designations will become clear in the next section). For instance, the mutant viruses CV, KV and PV were assembled into the mutant group Sa while complementary antibodies delineating epitopes that were predominantly modified by antigenic changes exhibited by this mutant group were assembled into a family of antibodies accordingly designated Sa-1 to Sa-15.

The resulting epitope map indicates that each mutant group characterizes an antigenic structure of the HA molecule which can undergo largely independent antigenic alterations. For example, mutations in the Sa mutant group affect the binding capacity of the Sa but not of the Ca antibody family and vice versa. Thus, adopting Urbanski and Margoliash's²⁰ definition of a discrete antigenic site as one to which the binding of specific antibodies is not affected by residue changes at the neighbouring sites, we tentatively designated these structures of the HA molecule as sites Sa, Sb, Ca and Cb. We stress that the reciprocal relationship between antibody families and virus mutant groups is only compatible with the notion that the mapping of antibodies is based on differences in antibody specificity and not on differences in avidity of antibodies directed against the same antigenic site. Also, the very low frequency of mutants selected in the presence of two antibodies directed against different sites further supported the notion of the independent mutability of these sites (unpublished observations).

Although most antibodies could be mapped to a single antigenic site, a few exhibited reduced binding to mutants assigned to different sites. In most cases, the observed overlap was between two sites (especially Sa and Sb) and, as discussed below, probably indicates the close physical proximity of these sites. In a few cases, however, linkages among three or four sites were observed. Notably, these linkages were only evident at the level

Table 2 The frequency of mutants in individual sites

Hybridoma antibody	No. of virus samples analysed	Frequency of mutants	
		In individual HA epitopes (log 10, mean ± s.e.m.)	Average per HA site
Sa-1 (C)	4	–5.59 ± 0.09	
Sa-4 (P)	1	–6.49	–6.14 ± 0.41
Sa-6 (K)	2	–6.08 ± 0.60	
Sa-15	3	–6.41 ± 0.33	
Sb-6 (E)	2	–5.32 ± 0.19	–5.48 ± 0.22
Sb-7 (B)	4	–5.63 ± 0.18	
Ca-1 (N)	5	–5.21 ± 0.34	
Ca-4 (D)	5	–4.86 ± 0.21	–5.31 ± 0.50
Ca-6 (S)	1	–5.85	
Cb-13 (L)	4	–6.26 ± 0.19	–5.98 ± 0.40
Cb-5 (R)	2	–5.70 ± 0.67	

Cloned PR8 virus was titrated in the allantois on shell culture system in the absence and presence of an 'over-neutralizing' dose of the indicated anti-HA antibodies¹⁵. Viruses that grew at the titration end point in the presence of anti-HA antibody were shown to be mutants by subsequent antigenic analysis. The mutant frequency (ratio of virus titre in the presence of anti-HA antibody to virus titre in its absence) was determined in several independently cloned PR8 virus samples. Letters in parentheses indicate the viral mutants selected (see Fig. 1).

these heterologous virus strains, suggesting a varying extent of antigenic drift in nature. The Sb antibody family is almost completely nonreactive with virus strains isolated after PR8. Thus, the antigenic site delineated by the Sb antibodies underwent drastic antigenic drift in nature while drift occurred to a slightly lesser extent in the Sa site, in which four cross-reacting antibodies react with heterologous viruses isolated shortly before (SW and WSN, in 1931 and 1933) or shortly after (MEL and BH, in 1935) the isolation of PR8. In contrast, drift occurred

in nature to a much lesser extent in the antigenic sites delineated by the Ca, Cb and Cx antibodies. (Based on these observations we have designated the PR8 'strain-specific' antigenic sites Sa and Sb and the 'cross-reactive' sites Ca and Cb. Note, however, that the Sa and Cb sites contain both 'specific' and 'cross-reactive' epitopes, although at different proportions.)

If antigenic drift in nature results from the selection of spontaneously arising mutant viruses that exhibit a favoured growth potential amid a pre-existing immunity in humans⁴, the mechanisms responsible for antigenic drift clearly act differently on the various antigenic sites defined here. This phenomenon is probably not due to an inherently greater mutability of the antigenic structures corresponding to the Sa and Sb sites as the average frequency of antigenic mutants present in cloned egg-grown PR8 virus is similar in 'specific' and 'cross-reactive' antigenic sites (Table 2). Therefore, the antiviral immune mechanisms seem to exert a stronger selection pressure for mutations in the Sa and Sb sites than the Ca and Cb sites. This could result from a predominant immune response of humans to the Sa and Sb sites and/or greater protective antiviral activities mediated by these antibodies.

Preliminary experiments showed that antibodies directed against the Sa and Sb sites exhibit *in vitro* a >10-fold higher virus-neutralizing potency than antibodies directed against the Cb site, which could explain the more extensive drift in the Sa and Sb sites than in the Cb site. However, very little drift occurred in the Ca site despite the relatively high virus-neutralizing potency of anti-Ca antibodies *in vitro*. Perhaps humans are unable to produce antibodies against the Ca site in sufficient quantities, or anti-Ca antibodies are ineffective *in vivo*.

We have thus used hybridoma antibodies and virus mutants selected *in vitro* to characterize the antigenic topology of the PR8 HA molecule. Webster and Laver¹⁹ have used a similar approach to demonstrate the existence of at least three non-overlapping antigenic sites on the HA molecule of influenza virus A/Mem/71. This approach has so far been used only to investigate the antigenic structure of the influenza virus HA molecule but it is clearly applicable to other viral proteins and to surface proteins of eukaryotic and prokaryotic organisms³⁰. Thus, it should be possible to determine the antigenic structure of a wide variety of biologically relevant antigens, which in turn may be useful for understanding the relationship between specificity and function of immune effector mechanisms.

We thank Maureen Carey, Dale McCreedy and Alex Taylor for help with these experiments. The study was supported in part by grants from the National Institute of Allergy and Infectious Diseases (AI 13989), the National Multiple Sclerosis Society (RG 851C6) and the Medical Scientist Training Program (GM 07170).

Short-lived cytoplasmic regulators of gene expression in cell cybrids

C. Ronald Kahn*, Roger Bertolotti, Maryvonne Ninio & Mary C. Weiss

Centre de Genetique Moleculaire du CNRS,
91190 Gif-sur-Yvette, France

Somatic cell hybridization is a valuable tool for investigating the control of gene expression in eukaryotic cells^{1–4}. Studies of hybrid cells, heterokaryons, reconstructed cells and cybrids (cytoplasmic hybrids) have suggested that cytoplasmic factors may be involved in this regulatory process. Unfortunately, studies of this kind usually require that hybrid or modified cells be maintained for some time in a selective environment during which chromosomal losses or other changes may modify the genetic functions of the cells and thus vitiate conclusions about the mechanism of gene regulation. We report here the preparation of cybrids between enucleated mouse fibroblasts (Cl-1-D) and differentiated rat hepatoma cells (Fao) and the use of a combination of histological techniques to identify these modified cells early after fusion without the use of selective media. We found that albumin production in most cybrids was suppressed (extinguished) at 12–20 h after fusion but was restored by 48 h. These results suggest that there is a cytoplasmic factor in the fibroblast which exerts negative control over expression of the albumin gene, but which in the absence of the fibroblast nucleus, is not renewed and therefore short-lived.

The loss of gene functions characteristic of differentiation is commonly observed after cell fusion and is termed extinction^{1,2,4–6}. For example, most hybrids between fibroblasts and hepatoma cells do not express differentiated liver functions such as albumin synthesis, tyrosine aminotransferase and aldolase. The phenomenon, well studied in hybrids, has also been observed in heterokaryons (refs 7–10 and M. Ninio and M. Weiss, in preparation), and it has been suggested that differentiated gene functions are controlled by diffusible substances whose effects are negative or suppressive^{1–3}. Evidence that the substances concerned may be cytoplasmic has been provided by experiments¹¹ in which cybrids obtained by fusing Friend erythroleukaemia cells with cytoplasm of neuroblastoma cells or fibroblasts failed to produce haemoglobin in circumstances in which erythroleukaemic cells would have done so. However, most attempts to transfer extinction or other properties under genetic control by hybridization have failed (refs 12–14 and C. R. Kahn, T. V. Gopalakrishnan and M. C. Weiss, in preparation). Such negative experiments, however, do not rule out the possibility of cytoplasmic regulators of gene expression, because the cybrids usually cannot be examined until several days to weeks after fusion when grown in selective conditions. Here we used a combination of histological techniques to search for cytoplasmic regulatory factors early after cybrid formation.

The cytoplasm of the mouse fibroblast Cl-1-D was labelled by allowing the cells to phagocytose polystyrene beads (0.5–1.0 µm), after which enucleation was performed using the method of Gopalakrishnan and Thompson¹⁵. Cl-1-D cells are somewhat resistant to cytochalasin-induced enucleation, but with this method between 50 and 70% of the cells can be enucleated with high yield. After a short period of recovery, the cytoplasts, still attached to the plastic disks used for enucleation, were fused with the differentiated rat hepatoma, Fao, using polyethylene glycol (PEG). At selected time intervals, the cells were fixed and stained by an indirect immunofluorescent technique for albumin⁹ followed by nuclear staining with the fluorochrome dye Hoescht 33258 (ref. 16). The cells were then examined using phase contrast and epifluorescent illumination.

This combination of histological techniques allowed the identification of both parent cell types, heterokaryons, hybrids and cybrids. The fibroblast cytoplasm was labelled with beads and the hepatoma was not; the rat (hepatoma) nuclei stained homogeneously with Hoescht 33258, whereas mouse (fibroblast) nuclei possessed densely staining heterochromatin or chromocentres which fluoresced as bright spots (Fig. 1, top and middle rows respectively). Heterokaryons possessed cytoplasmic beads and both rat and mouse nuclei; hybrids, cytoplasmic beads and a large 'mixed-type' of nucleus; and cybrids, cytoplasmic beads and only a rat nucleus (or nuclei) (Fig. 1, bottom row). Each of these cell types was evaluated for albumin production by immunofluorescent staining (Fig. 1c, f, i).

At 12–20 h after fusion, cybrids between the enucleated fibroblast Cl-1-D and the rat hepatoma Fao showed a marked extinction of albumin production based on immunofluorescent staining (Fig. 1i). In four separate experiments, 59–72% of all mononuclear (1N) cybrids examined were negative for albumin, compared with <10% negative in normal cultures of Fao (Table 1; Fig. 2). This is comparable with the frequency of extinction of albumin production observed in the same experiments in heterokaryons between intact Cl-1-D and Fao at this time point (data not shown). The extinction was not due to a toxic effect of the PEG or to the fusion itself because intact Fao cells on the same disk or Fao homokaryons (Fao cells fused with other Fao) were between 89 and 91% positive for albumin by this technique. Furthermore, the extinction was not due to quenching of fluorescence by the polystyrene beads, because Fao cells which had been allowed to phagocytose beads directly showed comparable levels of albumin by immunofluorescence (data not shown).

Extinction was a rapid but transient phenomenon (Fig. 2, Table 1); within 6 h after fusion, 18–35% of all cybrids already demonstrated extinction, and extinction reached its maximum by 12–20 h (Table 1). After 24 h, a decline in the level of extinction was apparent, and by 45–48 h cybrids were 90% positive for albumin, a level comparable with that in the non-fused Fao.

Although we cannot accurately quantitate the ratio of cytoplasm contributed by the enucleated fibroblasts and the intact hepatoma, some attempt was made to evaluate the concentration dependence of the phenomenon by comparing the frequency of extinction in cybrids containing one nucleus with those containing more than one nucleus (but only rat hepatoma nuclei). In each experiment, and at every time point, the frequency of extinction was greater in the one-nucleus cybrids (1N), than in cybrids containing more than one nucleus (>1N) (and thus more than one rat hepatoma cell) (Table 1, Fig. 2b). In general, extinction seemed to be more frequent in those cybrids containing the largest numbers of beads, although this proved impossible to quantitate because cytoplasts varied considerably in the extent of labelling and those more heavily labelled with beads were preferentially lost during the enucleation procedure. However, these experiments strongly suggest that the cytoplasm of the mouse fibroblast contains a diffusible regulatory molecule which is short-lived and can influence the expression of albumin production in a time- and concentration-dependent fashion.

* Permanent address: Section on Cellular and Molecular Physiology, Building 10, Room 8S-243, National Institutes of Health, Bethesda, Maryland 20205, USA.

Despite intensive study, the molecular basis for the regulation of gene expression during the process of cellular differentiation remains poorly understood. It has been assumed that there may be both positive and negative regulators of gene expression in eukaryotic cells analogous to those observed in bacteria¹⁷. The existence of cytoplasmic molecules which may serve as regulators of gene expression has been clearly demonstrated by nuclear transplantation in protozoa and lower vertebrate species^{18,19}.

More recently, evidence has also been provided for the existence of similar positive and negative cytoplasmic regulatory factors in mammalian cells. Analysis of differentiated functions in somatic cell hybrids¹⁻⁶ and heterokaryons (refs 7-10 and M. Ninio and M. Weiss, in preparation) has suggested that the expression of genes in mammalian cells may be regulated by diffusible substances whose final effect may be either negative (extinction) or positive (activation). Evidence that these factors exist in the cytoplasm has been suggested by two types of experiment. Lipisch *et al.*²⁰ observed activation of the gene for tyrosine aminotransferase in reconstructed cells prepared from

mouse fibroblast nuclei and rat hepatoma cytoplasts, and Gopalakrishnan *et al.*^{11,21} have observed both extinction and activation of differentiated functions in cybrids prepared from mouse erythroleukaemia cells and cytoplasts derived from a variety of cells. With these exceptions, however, most attempts to transfer cytoplasmic regulatory factors have yielded negative results¹²⁻¹⁴. For example, we found that 6 weeks after fusion, cell hybrids between hepatoma and fibroblasts almost invariably showed extinction of differentiated liver functions (such as albumin and α -fetoprotein production, aldolase activity), whereas cybrids prepared using only the fibroblast cytoplasm did not, although chloramphenicol resistance (a fibroblast mitochondrial marker) was transferred, indicating that fusion had indeed taken place (C. R. Kahn, T. V. Gopalakrishnan and M. C. Weiss, in preparation).

Our data suggest that the fibroblast cytoplasm does indeed contain a molecule(s) capable of producing extinction of albumin production with very high efficiency. The reason this potential regulator of gene expression was not previously observed is that, in the absence of a nucleus coding for new synthesis, the

Fig. 1 Morphological and immunological characterization of the parental cells and cybrids. Cl-1-D (middle row) is a clonal line of fibroblastic mouse cells, sometimes referred to as LM(TK)²⁸. Fao (top row) is a fourth-generation clonal line of well differentiated rat hepatoma cells derived from the hepatoma line H4IIEC3 which is resistant to 8-azaguanine and ouabain²⁹. Both cell lines were cultivated in modified Ham's F12 medium³⁰ supplemented with 5% fetal calf serum in a humidified atmosphere, 7% CO₂. To prepare cybrids (bottom row), Cl-1-D cells were first allowed to phagocytose polystyrene beads (Dow) by adding a sterile suspension to culture medium and incubating the cells overnight. Beads of 0.8 μ m were of optimum size for easy detection without gross distortion of morphology *d*, although 0.5 and 1.0 μ m beads were also usable. The cells were then detached with trypsin and EDTA²⁹, resuspended in phosphate-buffered saline (PBS), and 1 ml of cell suspension ($2-3 \times 10^6$ cells ml⁻¹) was allowed to attach to 45-mm plastic disks precoated with concanavalin A (0.15 mg) and enucleated as described by Gopalakrishnan and Thompson¹⁵ using medium containing 10 μ g ml⁻¹ of cytochalasin B. A 50-70% enucleation could be achieved by centrifugation for 40 min at 16,000g at 37 °C with a ~40-50% yield. After a recovery period of 30-45 min in normal growth medium, the medium was aspirated and 1 ml of a suspension of $2.5-3.5 \times 10^5$ Fao cells was carefully layered onto the plastic disk. After 2-2.5 h at 37 °C in the incubator, the Fao cells were well attached and fusion was carried out by treating for 1 min with a solution of 50% PEG (1000 Merck, Ultrapure) in serum-free medium. The cells were washed four times with serum-free media, then returned to the incubator in 60-mm Petri dishes containing 5 ml of growth medium. At appropriate intervals, the coverslips were removed and prepared for histological examination as described by Ninio *et al.* (in preparation). The cells were fixed in 3% formaldehyde for 1 min, which was diluted 1:1 with methanol, then replaced completely by pure methanol for 30 min. The cells were then incubated with a rabbit anti-rat albumin serum (dilution 1:100) for 30 min at 37 °C, washed with PBS for 5 min, then stained with a fluorescein-labelled sheep anti-rabbit IgG (Institut Pasteur, dilution 1:200) for 30 min at 37 °C. After an additional wash with PBS, the cells were stained with the fluorochrome Hoechst 33258 (0.5 μ g ml⁻¹)¹⁶ and rinsed again with PBS. Glass coverslips were mounted over the cells with buffered glycerol and sealed with Histolique. The slides could then be stored at 4 °C or examined directly in phase contrast and epifluorescent illumination using a Zeiss UV microscope equipped with a HBO 200 W mercury lamp. Photographs were taken with either a $\times 40$ or $\times 100$ oil immersion objective, using Ilford HP-5 or Ektachrome film. This figure shows the appearance in phase contrast and fluorescence microscopy of the two parent cell types and the cybrids: *a, d, g*, phase contrast; *b, e, h*, Hoechst 33258; *c, f, i*, albumin. Hoechst 33258 stains the nuclei of the rat hepatoma homogeneously (*b*), whereas the mouse fibroblast nuclei have a dotted appearance due to more intense staining of the chromocentres (*e*). The bottom row shows a typical cybrid next to a binucleated Fao cell or homokaryon. Both cells have only rat type nuclei (*h*), but the cybrid also shows cytoplasmic beads as a result of fusion with a Cl-1-D cytoplast. Note that albumin (*i*) is extinguished in the cybrid but not in the adjacent Fao cell.

Fig. 2 Time course of extinction of albumin production in cybrids between Cl-1-D fibroblasts and the rat hepatoma Fao. *a*, The experiments in Table 1 have been summarized by totalling all cybrids examined at each time point for the four experiments and calculating the per cent albumin-positive cells by immunofluorescence. Numbers in parentheses indicate the number of cybrids examined. *b*, The data in *a* were subdivided to show the mononuclear cybrids (1N, solid line) versus the cybrids with more than one rat nucleus (>1N, broken line). Note that at every time point extinction is more frequent in the 1N cybrids. We believe that immunofluorescent staining for albumin will be positive until the cellular content of albumin is reduced by >75%.

factor has a relatively short half life. Thus, albumin production was inhibited or markedly repressed in the majority of cybrids by 12–20 h after fusion, but by 48 h extinction was no longer observed, presumably because the factor had been metabolized or diluted by cell division to a level no longer sufficient for activity. This is supported by data obtained in a parallel series of experiments in which heterokaryons between Cl-1-D and Fao cells showed extinction with a similar rate of onset, but which persisted for the 10 days of the study (M. Ninio and M. C. Weiss, in preparation). Although quantitation is difficult, both studies showed a dose-dependent effect; cybrids and heterokaryons with more than one hepatoma nucleus showed less extinction than those with only a single hepatoma nucleus.

Neither the chemical nature of the factor(s) nor the location of regulation is apparent. Previous studies with hybrids and mutant cells have suggested that regulation of gene expression occurs at a pretranslational level and is specific for the differentiated functions of the cell^{1–6}. Studies in prokaryotes have indicated that both proteins and small molecules, such as cyclic AMP, may act as regulatory factors¹⁷. The time course of extinction observed in these experiments is more consistent with the half life

of a protein than a cyclic nucleotide. However, it would not be surprising if the time course of effect varied extensively depending on the half life of the regulator in its new environment, as well as its mode of action. Activation of the tyrosine aminotransferase gene in the reconstructed cells formed from fibroblast nuclei and hepatoma cytoplasm lasted 6–8 weeks²⁰, and permanent activation of the gene for phenylalanine hydroxylase seems to occur in cybrids formed from erythroleukaemia cells and hepatoma cytoplasm²¹. However, using an experimental design similar to that reported here, except that cybrids were formed between enucleated hepatoma cells and fibroblasts, we have been unable to obtain evidence for any positive regulators of albumin gene expression.

Clearly, some cytoplasmic regulators of gene expression exist. The transient effect observed in the absence of the nucleus supports the concept that, in general, the epigenotype is stable¹. Thus, somatic-cell hybrids re-express parental differentiated functions following the loss of chromosomes from the extinguishing parent^{22–25}. It is also evident, however, that, in the eukaryotic cell, there are multiple potential mechanisms of gene regulation. Direct studies of cell extracts using chemical

Polyoma DNA sequences involved in control of viral gene expression in murine embryonal carcinoma cells

Michaël Katinka*, Marc Vasseur†, Nicole Montreau†, Moshe Yaniv* & Daniel Blangy†

Polyoma virus can develop lytically in differentiated mouse cells, but is unable to express either early or late functions in undifferentiated early embryonic cells¹ or in embryonal carcinoma (EC) cells of the mouse. However, the EC cells become susceptible during differentiation and then behave as do mouse somatic cells². We have recently described the isolation of a new class of polyoma virus mutant (Py EC) able to develop normally in an EC cell line (PCC4-Aza) that is capable of trigeminal differentiation *in vivo*³ but exhibits a very limited differentiation *in vitro*⁴. The mutants do not grow in another EC cell line (F9) that is 'blocked'—'nullipotent' *in vivo*, but able to differentiate *in vitro* when grown in the presence of chemical inducers. Compared with their parental strain, all Py EC genomes analysed so far have an extra 20-50 bases in their *HpaII*-3 restriction fragment⁵. We now describe polyoma mutants that will grow in EC F9 cells, and the sequence changes in two of them. The region involved in the mutations can be folded into a putative tRNA-like secondary structure which may be involved in the regulation of viral early transcription with respect to the state of differentiation of the host cell.

Mutants of polyoma virus able to develop on F9 EC cells were obtained using two different procedures. F9 cells were infected (1) with an heterogeneous and highly defective polyoma stock, obtained by viral propagation at high multiplicity of infection (MOI) on permissive mouse cells, as already described for the

selection of Py EC on PCC4-Aza, or (2) with purified wild-type polyoma A2, at a MOI of 5,000 plaque-forming units (PFU) per cell. Following their infection, F9 cells were cultured as usual and scored periodically by immunofluorescence for polyoma T (tumour) and V (late structural proteins) antigen expression. In both procedures, and as reported for the PCC4-Aza cells, viral proteins were detected in 5-20% of the cells 3-4 weeks after infection. The virus produced was recovered and plaque purified three times on secondary mouse embryo cells (We propose calling the mutants Py EC, followed by the name of the cells on which they were selected and the isolate number, for example, Py EC PCC4-97, Py EC F9-5). Transforming ability on rat FR3T3 cells⁶, efficiency of tumour induction in newborn hamsters and burst size on various permissive mouse cell lines were checked for independent Py EC F9 isolates. As observed in the case of Py EC PCC4, no significant difference between Py EC F9 mutants and wild-type virus could be found.

Endonuclease restriction analysis of five independent Py EC F9 mutants revealed no common detectable size modifications of the *HpaII*-3 fragment (compare the EC PCC4 mutants of ref. 9) nor any specific rearrangement associated with either of the selection procedures used.

F9 EC cells infected with 10 PFU of any of the Py EC F9 mutants tested, exhibit, 42 h after infection, more than 60% of T-antigen positive cells, as measured by immunofluorescence⁸. In the same conditions of infection, never more than 5% PCC4-Aza cells were shown to express T or V antigen (results not shown).

The efficiency of F9 infection by the Py EC F9 mutant can be compared with that of PCC4-Aza infection by Py EC PCC4 mutants⁹ in the latter case, at 37 °C, never more than 40% T- or V-antigen positive cells were observed (after infection at 100 PFU per cell) whereas F9 cells infected at 5-10 PFU with Py EC F9 mutants allow viral expression in 60-80% of the cells. All these biological properties suggest that restriction of polyoma expression in F9 and PCC4 may involve different factors.

The cloned viral genomes inserted into the *Bam*HI site of PBR322 were tested for their infectivity by transfecting secondary mouse embryo cells with viral DNA obtained after cleavage with *Bam*HI and ligation. The virus burst obtained was then used to infect both EC F9 and EC PCC4 cells at a MOI of 10-20 PFU per cell. When monitored for the appearance of T and V antigens by immunofluorescence, 60-80% of the EC F9 cells but only 3-5% of the EC PCC4 cells were positive. DNA extracted from two mutant infectious viruses revealed the expected restriction pattern, without apparent defective genomes.

About 500 nucleotides around the origin of DNA replication were sequenced in Py EC F9-1 and about 700 in Py EC F9-5, as described in the legends to Figs 1 and 2. Only slight differences from the wild-type polyoma sequence were found. Py EC F9-1 has three insertions: a thymine between positions 85 and 86, another thymine after position 109 and an adenine between positions 119 and 120. One transition of a thymine into a cytosine at position 63 is also observed (The numbering system used here is based on the PyA2 sequence of Arrand *et al.*¹⁰ where residues in the late region are counted from the middle of the *HpaII*-3/5 taken as zero). In Py EC F9-5, there is a duplication of a 179-base pair region covering the origin of DNA replication but only the right-hand duplicated sequence reveals the existence of two supplementary nucleotides, a thymine inserted between positions 108 and 109 and an adenine between nucleotides 120 and 121. We do not believe that the duplication in Py EC F9-5 has any role in the properties of the mutant because other polyoma mutants with a duplication of the DNA origin of replication¹¹ do not give rise to productive infection on either EC F9 or EC PCC4 cells. The rest of the nucleotide sequence is identical to the one we have determined previously for the A2 wild-type polyoma¹², and differs only slightly from that published by Arrand *et al.*¹⁰. To confirm that the host-range capacities were due solely to the point mutations detected, and that no other modification elsewhere in the polyoma genome

Fig. 1 Genomic organization around the origin of DNA replication in wild-type and mutant polyoma, the DNA sequencing strategy. The origin of DNA replication is commonly given as the *HpaII*-3/5 junction. The beginning of translation of the early T antigens at -173 base pairs and the late VP2 at +291 base pairs, as well as its direction are shown by the corresponding arrows. Underneath are given the parallel regions of the two mutants analysed in the present study. The nucleotide sequence determined is presented by the underlying arrows. For both mutants, the *HpaII*-3, *HpaII*-5 and *BglII*-3 fragments were purified on polyacrylamide gels after digestion of the corresponding pBR322-Py plasmids, and labelled at their 5' end with ^{32} P using the exchange reaction with T_4 polynucleotide kinase as described by Berkner and Folk²⁰.

After secondary restriction with *Bam*HI, *Alu*I and *Bam*HI, respectively, the labelled and purified fragments were submitted to the partial chemical degradation of Maxam and Gilbert²¹ and the subsequent products were fractionated on 6 or 20% polyacrylamide-urea 0.35-mm thin gels²². Autoradiography was done either with Kodak NS-2T film at -20 °C or with an intensifying screen (Cronex Lightning-Plus, DuPont) using a preflashed Kodak X-OMAT R film at -70 °C (ref. 23). Point mutations observed are shown (▼). The duplication in polyoma EC F9-5 is designated by the box.

was involved, we constructed a hybrid DNA molecule in which the mutant *BglII*-*Bam*HI 750-base pair (930 base pairs in Py EC F9-5) fragment covering the mutated region was ligated to the complementing 4.5-kilobase region of wild-type polyoma, and vice versa. The hybrid DNA was used to transfect secondary mouse embryo cells and the virus burst was utilized to

infect EC F9 cells. Only the hybrids containing the 750-base pair (or 930-base pair) fragment from the mutants gave productive infection as assayed by the appearance of the T and V antigens (about 60–80% positive cells compared with 0.1% in the opposite construction). Segal *et al.*¹³ have detected a low amount of unspliced SV40 DNA in F9 cells after infection with

Fig. 2 Nucleotide sequence of Py EC F9-1 and of Py EC F9-5. The insertions (▲) and transitions (▼) in the mutant sequences are shown. The restriction sites for *BglII*, *HpaII* and *PvuII* are given as landmarks. The numeration of the nucleotides follows that of Arrand *et al.*¹⁰

this virus. The fact that the polyoma mutants are not located in the region concerned with the splicing of polyoma early RNA tends to exclude a possible block at this step during infection with wild-type polyoma.

The changes occurring in the Py EC PCC4 and Py EC F9 mutants show that both groups have genomes altered in the sequence of the *HpaII*-3 fragment, near the origin of DNA replication on the late side of the genome, in a noncoding region (Fig. 4). Py EC PCC4 mutants reveal a genomic rearrangement in which a deletion (from nucleotide 46 or 77 to nucleotide 107) is replaced by the duplication of a downstream region (nucleotide 138 or 157 to 220, see Fig. 4 and ref. 12), whereas the Py EC F9 mutants exhibit in the same region a series of point mutations as described above. Note that in the Py EC F9 mutants, one of the thymine insertions is always located at the 108/220 deletion-duplication junction site of Py EC PCC4 mutants. The region of the polyoma genome comprising nucleotides 62–133 can be folded into a clover-leaf structure (ref. 5 and Fig. 3). The generation of such a structure with circular double-helical DNA is certainly subject to topological constraints. However, transcription activation postulated for prokaryotic replicons¹⁴ or the action of a DNA gyrase (DNA topoisomerase II)^{15,16}, could permit the local melting of the DNA double strand and the formation of a secondary structure with single-stranded DNA. The structure can be stabilized by interaction with specific proteins. Alternatively, a secondary structure on the DNA level could be limited only to stem II (Fig. 3). It is striking that this part of the genome is modified in both Py EC PCC4 and Py EC F9. In Py EC F9, all the mutations are localized between nucleotides 63 and 121 (see Figs 3, 4) and touch mainly stem II of the clover-leaf structure, with the insertion of an adenine facing a complementary thymine. Such an insertion of an extra A-T base pair in a G+C-rich stem could change its interaction with proteins.

Whereas transcription *in vitro* with eukaryotic RNA polymerase II requires mainly the TATA box (D. Hogness and M. Goldberg, unpublished observations), several pieces of experimental evidence suggest that at least 100–200 nucleotides upstream of this sequence are important for transcription regulation *in vivo*^{17,18}. The rearranged region in the polyoma EC mutants is located 100–200 nucleotides before the hetero-

Fig. 4 Summary of the genomic changes around the origin of DNA replication in Py EC PCC4 and Py EC F9 mutants. The upper part of the diagram shows the rearrangements in the Py EC PCC4 mutants where a region between nucleotides 46 or 77 to 107 is deleted and replaced by the region between nucleotides 138 or 157 to 220 which is duplicated (see also ref. 12). The lower part concerns the Py EC F9 mutants with the point mutations (▲) between nucleotides 63 and 121 as described in the text.

geneous 5' ends of the early mRNA (R. Kamen, personal communication). In addition, this same region precedes the 5' ends of late mRNA and should be important for the control of late transcription. Thus, the sequence rearrangements that can occur without impairing the viability of the virus are limited. Previous studies have shown that wild-type polyoma DNA penetrates the EC cells but does not express early mRNA. Recent results¹⁹ reveal that on polyoma EC viral infection of PCC4 or F9, no new sites for early polyoma transcription initiation could be detected but the overall rate of specific polyoma transcription is greater than that of wild-type polyoma in these cells.

A model could be proposed in which a regulatory protein present in EC cells but not in differentiated derivatives inhibits early transcription of the virus by binding to the nucleotide 63–132 region. The modification of the sequence either by point mutations or by rearrangement destroys the specific binding site but still conserves a stable secondary structure otherwise needed for viral expression, thus relieving the inhibition of transcription. Alternatively, another model could be constructed based on a positive regulation. Interestingly, the putative tRNA-like structure in which the mutations occur is included in the region devoid of nucleosomes (gap) in viral chromatin (P. Herbomel *et al.*, unpublished results).

We thank C. Kress for assistance, C. Maczuka for help in the preparation of the manuscript, and A. Minty for valuable criticism of this manuscript. This work has been supported by grants from the French Centre National de la Recherche Scientifique, the Institut National de la Santé et de la Recherche Médicale and the Délégation à la Recherche Scientifique et Technique.

Fig. 3 A clover-leaf structure in the late noncoding region in the polyoma virus genome. The structure suggested by Soeda *et al.*⁵ for wild-type polyoma virus between nucleotides 62 and 133 on the late strand of the genome is drawn. It is possible to draw the complementary structure with the early strand. The insertions and the transition in this region in the two mutants analysed are shown. Note that most insertions for both mutants occur on stem II, always with a double insertion of the complementary adenine and thymine. Note also that in all the Py EC PCC4 mutants, the junction between the deletion and the duplication at 108/220 occurs again on the stem II¹².

New guard at the National Academy

The annual meeting of the National Academy of Sciences in Washington this week is something of a milestone. Among other things, the scientific programme includes a meeting to mark the impending retirement of Dr Philip Handler as president of the academy. From then until 1 July, when Dr Frank Press takes over, he will be something of a lame duck, which does not mean that he will be less outspoken than in the past (President Eisenhower, one of the most taciturn and even inarticulate of presidents, waited until his lame-duck period before making his unexpected but still memorable attack on the "military-industrial complex"). Inevitably, however, the academy's army of committee members will from now on be guessing at the changes that Press's succession is likely to bring. Handler will have to try harder if he seeks to capture their attention.

He should not feel slighted. Handler has done a distinguished job in his two six-year stints as president of the academy. Neither of his immediate predecessors could have done as well. Dr Detlev W. Bronk's apparently randomly directed ebullience may have suited the spirit of the late fifties and early sixties, but would have landed him perpetually in hot water in the past decade. Similarly, Dr Frederick W. Seitz's masterly passivity, well suited to the booming budgets of the mid-sixties (but wearing thin towards the end) would have led him into trouble in the turbulent seventies. Handler's spell at the academy has been a much rougher ride. During this period, budgets have been falling, Congress has assumed much more explicitly than before the role of public watchdog over — some would say public prosecutor of — the scientific enterprise, which has also been threatened by the environmental nonsenses of the early 1970s and the fuss about genetic manipulation at the end of the decade. Inevitably, Handler has frequently been forced to play defending counsel. To his credit, he has done this job courageously — and in the process has made some stirring speeches.

Unlike the scientific academies of Western Europe, the United States academy has the seeds of dissension built into its constitution. Thus it resembles the academies of Eastern Europe in having a formal relationship with Congress, which is empowered to commission studies on whatever questions happen to flit across the scene. If, for example, Congress wishes to know whether small doses of radiation are dangerous, whether the accumulation of chlorofluorohydrocarbons in the atmosphere will dangerously deplete the ozone layer or whether the Department of Energy is telling the truth about energy forecasts, many committees of Congress will think first of commissioning a study from the academy. Technically, the work is done by the National Research Council, in whose management both the academies of engineering and medicine have a part, but in the public mind (and that of Congress) the academy of sciences is responsible. Since by definition the subjects on which Congress asks for advice are contentious, the academy frequently finds itself at the centre of public argument. Last year's report on the effects of small doses of radiation (see *Nature* 286, 550, 1980) was a good illustration of the troubles that can arise. Occasionally, the academy asks for trouble, as with its own committee's pungent advice that people should not be unduly concerned with the exact composition of what they eat (see *Nature* 285, 428, 1980). One of Handler's tasks, in the past twelve years, has been to give this stream of documents a collective stamp of authority. For the future, it would be better if the academy could arrange to shuffle off commissions for studies which are either pointless or untimely. Too much of what it has attempted should have been

refused, and should be in the future.

That is one task for Dr Frank Press. Another is to redefine the ground on which the scientific enterprise is defended. Hitherto, the academy's machinery for cogitating about problems of general concern has been directed towards specific contemporary problems, where data gathered by research promise to illuminate matters of general interest. The academy has been much less concerned with the machinery by which the scientific enterprise is sustained. The education of students in schools and colleges? The National Science Foundation has been allowed to set the pace, at least until its budget was slashed last month. The problem of university scientists, with or without tenure, engaged in the increasingly hazardous gamble of the pursuit of scholarship? Leave that to the American Council on Higher Education, which has strong opinions on issues such as tenure — and hope that people will one day recover from the over-abundance of documents churned out by the Kerr commission on higher education. The propriety of the arrangements academics make with their universities to share in the profits of extramural commercial enterprises? Or that universities make with commercial companies or with agencies of the federal government? The universities, the argument seems to go, are too jealous of their independence to welcome advice.

As events have turned out, the academy in Washington should move quickly to take up these and a host of related questions. Although the competitive universities and colleges of the United States are rightly proud of their autonomy, they are now afflicted by so many common and pressing problems that the academy's influence could be decisive. Should the protest against the new strict interpretation of the rules prohibiting the export of military material, which threatens to restrict the education of overseas graduate students, be left to a handful of college presidents (see *Nature* 9 April)? Are the new rules introduced by the Office of Manpower and Budget for accounting for the use of federal funds equitable or merely iniquitous? And will they achieve their declared purpose of saving federal dollars? Is it sensible that sources of financial support for graduate students should be as much curtailed as in the past few years? What — in the national interest as well as that of research — should be the balance in the funding of research between project grants (with their accompanying variable overhead percentages) and straight institutional support (of which there is at present almost none)? And if institutional support comes back into fashion, to which institutions should it be channelled by which agencies? Many of these are tedious questions, but they are much more important than the consequences of aerosols in the atmosphere.

The surprise so far is that the academy seems to have had very little interest in these issues. They are of course intangible and often boring. There is also always the danger that if a body such as the National Academy of Sciences speaks out forthrightly on these subjects, it will be accused of self-serving propaganda on behalf of its members. That risk is worth running. Indeed, the risk must be run. For with so many other well-wishers of the scientific enterprise emasculated by President Reagan's first budget, the academy is almost the only institution in Washington able to speak out. Moreover, the issues are likely to induce a harmony of purpose among the members of the academy sufficiently strong to carry the institution through the divisive issues certain to crop up in the next six years as in the past twelve — whether, for example, to protest at Sakharov's exile and, if so, how? Is this an agenda for Dr Frank Press?

Will the London Zoo survive (and how)?

The London Zoo, more formally known as the Zoological Society of London, is in serious trouble. In the annual report for 1980, published last week, the president of the society, Lord Zuckerman, says that the organization is "up against a brick wall". The evidence of the report leaves little doubt that he is correct. Last year, the society made a loss of £666,000, more than 13 per cent of its income of just under £5 million. This, however, is not the end of the tale. The society has made large losses in previous years — £130,000 in 1979, for example. The novel but ominous implication of last year's result is that the society's bank balance has been almost emptied, and replaced by a substantial overdraft. And that there are unmistakable signs that the chief source of revenue, the entrance fees paid by visitors to the two zoos, in Regent's Park, London, and at Whipsnade, is no longer an inexhaustible pot of gold. For at least two decades, as charges have been increased, the numbers of visitors to the zoos have been falling. Last year, attendance at Regent's Park fell by 11 per cent. Like many other enterprises in inflation-ridden Britain, the society (which is a charity and not technically a business) is being crippled by continually rising costs and the shortage of cash in the economy to spend on the services it provides.

The society's recipe for survival, outlined in the report for 1980, is logical enough but almost certainly destined for failure. The zoo, the argument goes, is constituted as a charity which provides public services of several different kinds — pleasure for visitors to the two zoos, educational experience for a great many school students and a substantial amount of scientific research, much of it distinguished and not all of it inspired by the veterinary needs of the animals on display. Last year, the two zoos managed to collect some £60,000 on account of their overtly educational work, by almost any test a miserly recompense for their educational value not merely in London but in the United Kingdom as a whole. Last year, the cost of research (£780,000) exceeded by £322,000 research grant income. So the society is asking why its value as an educational institution should not be more tangibly recognized by local and central government, and why a substantial part of the cost of its research must continue to be met by those who innocently spend an afternoon looking at exotic animals. On both counts, the zoo has a powerful case.

If the zoo were to go out of business — and if its financial position does not improve, it may have no choice — there would be a great outcry from all kinds of interested parties. Local education authorities would be prominent among those protesting that a great institution should not be allowed to sink without trace. They would be complaining that children in their schools would be deprived of an essential part of their education. The spendthrift among them would no doubt argue that if the London Zoo should be closed, it would be necessary for public funds to pay the cost of carting children to the distant game parks of central Africa. Some might even be able to raise the funds. The zoo's case is that if the local authorities are as certain as seems likely to mourn the disappearance of the London Zoo (and perhaps also of Whipsnade), they should contribute more generously now to help keep both institutions in being. The logic is impeccable. The snag is that local authorities are just now as hard-pressed as the zoo itself. And in the nature of British local government, they are incapable of making discretionary expenditure, however prudent. Voluntarily to shoulder part of the cost of supporting the London zoos would be politically risky, but the same local governments (the Greater London Council and the Inner London Education Authority) would have no qualms in foisting on their ratepayers the much larger cost of salvaging the society's collapse.

The obstacles to the zoo's case for more outside support for its research programme are a little less ominous. The point has already been established that for two years there should be a modest subvention (£134,000 last year) from central government funds, while the zoo's laboratories can compete for project grants

from public and private sources. The accounts for 1980 (which sensibly charge the cost of research "of direct benefit to animal management" against the income of the public exhibits) nevertheless show that the society had to spend £250,000 of its inadequate income on research. The principle that a private organization should qualify for a public subvention towards the overhead cost of research is unusual but is not an outrage. If a research programme is worthwhile, there is no reason why it should not qualify for public support as if it were carried out in some publicly owned laboratory. The obvious snag, that private management may mean fickle management, is easily overcome by making sure that all grants are short-term grants. In the zoo's present plight, the Advisory Board on the Research Councils, which unimaginatively cuts the annual research cake in Britain, should be willing to do more to help.

Public support of this kind, however, can only be a stop-gap. The zoo itself must acknowledge that its research institutes cannot prosper if they have to live from hand to mouth, keeping watch on the dwindling queues at the visitors' admission gates. It is now clear that the zoo's laboratories have a modest if distinctive contribution to make to some intriguing problems in animal physiology and veterinary medicine, but that they will never be comprehensive or dominating. In the interests of the laboratories, the zoo should therefore seek a more durable framework for its research. For a year now, there has been talk of a consortium including the zoo, the British Museum (Natural History) — which should simplify its name as well as root out cladistic excesses from its public exhibitions — and the Royal Botanic Gardens at Kew. All three institutions have in common their dual concern for public exhibition and scientific research. The connections between the three research programmes are by themselves, however, probably too tenuous to be a durable bridge. Nor is it likely, in present circumstances, that other British zoos would be willing to regard the London Zoo as a central research service for them all, writing cheques accordingly. The zoo's research enterprise might be better able to make its way in the world by setting itself up as a common service for academic and public research laboratories, for example by setting up well-run breeding colonies of primates. Either (or some other) way, the zoo must quickly work out a plan and set out to make it work. In the process, it may find it prudent to put more distance administratively between the research laboratories and the Zoological Society of London as a whole. There is no evidence that the fellows of the society who go to watch the pandas on Sunday mornings presume to interfere with the research, but these days a show of independence would do no harm.

Much the same would be necessary if the zoo were to succeed in recruiting support from local government to keep its zoological display in good shape. Local government politicians are more convinced than others that money means power, in this case influence over exhibition policy. Lord Zuckerman seems bent on persuading London's local politicians that they should follow the examples of their peers in Berlin, Rotterdam and elsewhere. Would he and the council of the zoo be prepared to share their present absolute power with those willing to keep the zoo out of the red? This unfamiliar thought is neither unthinkable nor unseemly. In the long run, it would help and not hinder if local governments were prepared to share anxieties about the zoo as well as support for it. Experience elsewhere suggests that the propriety of the display need not be damaged. The implication is that the zoo should evolve into a consortium of three separate charities — a research organization, a scientific society of some importance and a public exhibition. In these hard times, it is too dangerous to let the enterprise stand or fall as a whole. That way, it would be better organized for survival, better able to provide its well-wishers with a sense of belonging to a constituency. After all, many of the society's friends think it wrong that animals should be kept in zoos.

Vienna institute hit by espionage charges

Claims force Soviet official to resign

Allegations of espionage for the Soviet Union have forced the resignation of Dr Arkady Belozеров as secretary of the Institute of Applied Systems Analysis at Laxenburg, near Vienna. This dramatic development has intensified anxiety at the institute about its long-term financial security, already threatened by the Reagan Administration.

Dr Belozеров was appointed to his post at the institute in 1971, and took up his job in December that year. An article in the British news magazine *Now* on 10 April said that Dr Belozеров, a plasma physicist by training, was also an agent of the KGB who had been the Soviet contact with a Norwegian double agent during his spell in Vienna. A statement put out by the institute on 15 April said that Dr Belozеров had offered his resignation and that this had been accepted.

The responsibilities of the secretary of the institute are largely those of external relations with member organizations (mostly national academies), potential donors (such as foundations) and the press. As with other senior posts at the institute, the secretary is appointed jointly by the director and the governing council. Dr Belozеров's name was the only nomination before the council in 1979. The institute's policy on recruitment requires that there should be a national balance among senior members of the staff.

The allegation in the *Now* article is that Belozеров took over from another Vienna-based Soviet agent responsibility for keeping contact with a Norwegian petroleum engineer known as Jansen. According to the magazine, "Jansen" began working as a double agent for the Norwegian security services six years ago, providing a succession of Soviet contacts in Oslo and then Vienna with innocuous and sometimes misleading information about petroleum operations in the North Sea and the China Sea.

Dr Belozеров is reported to have met "Jansen" on several occasions in Vienna, to have been incompetent in making arrangements for meetings and to have been reluctant to pay for information provided until its authenticity had been checked. He is reported to have given a full account of his career as a member of the KGB and in the process to have revealed the identity of a Soviet agent in Austria. His meeting with "Jansen" arranged for 4 April outside the Volks Opera in Vienna is said to have been frustrated by the expulsion of another alleged Soviet agent

from Norway.

In his letter of resignation to the institute, Dr Belozеров protests that the allegations "are without factual basis", but that there is no impartial forum in which he can demonstrate them to be false. His letter says that he offered his resignation "in the interests of the institute".

The institute says that Dr Belozеров's conduct of his post as secretary had been "completely satisfactory" but that it has no way of independently determining the truth of the allegations against him and therefore had no choice but to accept his resignation. A spokesman said last week that in the present precarious financial circumstances, any member of the staff against whom allegations of this kind were made would be asked to leave.

One curious feature of the Belozеров affair, as reported, is that Soviet agents should have been willing to pay for information about oil technology in deep waters

such as those of the North Sea when the institute itself had only recently published an up to date account of the field.

The Austrian government, an enthusiastic benefactor of the institute, has reacted protectively. The Minister of the Interior, Mr I. Lanc, said last week that Belozеров had committed no offence under Austrian law and complained that "certain countries" not having common frontiers with the Soviet Union had come to undervalue détente and to regard the Institute of Applied Systems Analysis as an expendable target.

The institute's financial prospects are not nearly as bright as they may have seemed only a few months ago. Although the member organizations of the institute are national academies, most of these are reimbursed by their governments for the cost of membership. The Soviet Academy of Sciences and the United States National Academy of Sciences are the largest con-

Schuster quits as EEC research director

Brussels

The reshuffle of top jobs at the European Commission following the appointment of commissioners and the allocation of their portfolios at the beginning of 1981 has led to a flurry of resignations during the past two weeks, and rumours that some directorates-general are to be reorganized are gathering force.

Five directors-general are known to be leaving, among them Gunter Schuster, head of Research, Science and Education (DG XII). His resignation was handed in amid speculation that he is dissatisfied with the way responsibility for DG XII has been split among three commissioners. At the beginning of the year, infighting among the new 14-man Commission caused a messy distribution of the research portfolios. Etienne Davignon (France) grabbed research and science, leaving Ivor Richards (United Kingdom) with education and training, and Karl-Heinz Narjes (West Germany) with industrial innovation.

Some members of the Commission claim that this arrangement is not as awkward as it might seem — decisions taken by the commissioners have in any case to be unanimous. The real reason for Schuster's departure may be that at 62 he would be due for retirement mid-way through the next four-year indirect action programme now being planned. A new man would be able to see the plan to completion.

His departure leaves a vacuum hard to fill. According to a close colleague, Herbert Allgeier, Schuster's greatest personal achievement was to build up from scratch the European Community's research policies from the shambles that followed the collapse of the Euratom programme at the end of the 1960s. Pressure is now being brought to bear on Davignon to

find a replacement as soon as possible, so that the new appointee can help draw up the new research policy guidelines.

Among the names being mooted is that of Fabrizio Caccia Dominioni, at present looking after research, development and nuclear policy. However, somebody may well be brought in from outside, although probably not another German or Briton. Leonard Williams of the

Schuster leaves the scene

energy directorate-general is being replaced by Christopher Audlands. In the best Byzantine traditions, the top jobs are distributed so that national pride and influence are not diminished with each four year reshuffle.

Other changes are rumoured, but one decision, it seems, has definitely been taken. The Environment and Consumer Protection Service (ECPS) is to be elevated to directorate-general status thanks partly to the patronage of the European Parliament. The ghostly DG XI, which was left vacant after an earlier round of administrative musical chairs, will once more have an occupant. Michel Carpentier will remain in charge as head of ECPS and will henceforth be officially addressed as director-general.

Jasper Becker

tributors at rather more than £1 million each a year

In the United States, the National Academy's annual contribution has since the inception of the institute been met by the National Science Foundation from its allocation of funds for international activities, cut in President Reagan's first budget from \$15 million to \$10 million for the coming financial year. After protests from the academy that the statutes of the institute require twelve months' notice of withdrawal, the putative contribution for 1982 has now been restored to the foundation's budget, but on the strict understanding that this will be the last contribution to be sanctioned by the Administration.

In principle, there is no reason why the academy should not seek to raise its annual contribution from some other source than the United States government, but in present circumstances this will not be easy. The 1982 budget for the institute will be agreed between the member institutions at two council meetings to be held in June and November this year. The United States academy will have to give notice of intended withdrawal at the end of this year if it is not by then assured of funds with which to pay its 1983 subscription.

It is ironical that the institute, founded partly with the intention of providing a place at which people from East and West could work on problems of international importance, should have run into trouble because of allegations of espionage.

US graduate employment

Industry has jobs

Washington

Despite continued uncertainty in the US economy, business is booming for engineering graduates — and natural scientists are not far behind. Figures just released by the College Placement Council of Bethlehem, Pennsylvania, reveal that engineers who expect to graduate this summer are already being offered starting salaries of up to \$26,000, a 10 per cent increase over last July. Graduates in physical and Earth sciences were being offered \$22,000, an 18 per cent rise compared with last year.

This rapacious demand for technical graduates has been confirmed by a report from a New York consulting firm, Deutsch, Shea and Evans, which claims that there has been a sharp up-swing in employment prospects for graduate engineers since last November. And the figures are in marked contrast with starting salaries for arts graduates, which average about \$12,000, with many failing to find any jobs at all.

The shortage of engineers is partly a reflection of declining enrolments in university engineering schools. For example, 2,751 engineering doctoral degrees were awarded in 1980, compared

with 3,074 in 1972, although this also reflects the fact that fewer engineers are staying on to do graduate work, the 1980 figures include more than 60 per cent foreign students, many of whom were not expected to stay in the United States.

Recruitment difficulties have also produced near-crisis in the engineering schools, few of which can afford to match salaries in industry. According to William A. Cox, president of the National Society of Professional Engineers, there are now 1,800 unfilled faculty positions in engineering schools — a situation which has led the society to add its voice to those asking Congress for federal assistance to upgrade facilities and research equipment to make the educational environment more attractive.

There is also a feeling that the turnaround in demand for technical graduates reflects greater optimism in the economy than six months ago. "In general, the market in technical areas is the best that it has been for years", says Victor Lindquist, director of the placement office at Northwestern University which carries out regular surveys of employment prospects. He claims, for example, that metal companies such as mining and steel, sectors which are likely to benefit directly from a significant increase in military spending, seem to be stockpiling talent in anticipation of a quick recovery in the economy.

The College Placement Council survey revealed that, as in the past, engineers represent the hottest buy in the employment market. More than 63 per cent of the job offers reported in the survey as having been received by mid-March were to future engineering graduates, although these only made up 7 per cent of the bachelor degree graduates in 1980-81.

In proportional numbers of offers, the scientific disciplines were dominated by computer science graduates, another field where demand is considerably in excess of supply, a point which has been made recently by the National Science Foundation. However, the average starting salary offered to such graduates of \$19,968 was considerably lower than the \$21,912 offered to graduates in physical sciences.

Among masters level graduates, the highest offers went to chemical engineering graduates, with an average starting salary of \$26,240 — almost 13 per cent higher than the figures last July. Geology and related geological sciences, in strong demand in the petrochemical and mining industries, ranked second with an average salary of \$25,380. All these figures are based on offers reported by placement offices at 161 US colleges and universities.

Figures released last week by the National Science Foundation reveal that there is an increasing tendency for graduate scientists, engineers and technicians to enter service rather than manufacturing industries. These industries accounted for 60 per cent of the total growth of employment for graduates in the three categories

between 1978 and 1980, even though only accounting for 40 per cent of the total employment.

Total science and engineering employment in private industry was virtually unchanged between 1970 and 1980, but this trend may be reversed, however, if the current patterns of employment for this year's graduates is maintained.

David Dickson

Soviet space programme

No shuttle yet?

The high cost of space research is troubling Soviet planners as well as their counterparts in the space agencies of Europe and the United States. At a ceremony on 10 April commemorating the twentieth anniversary of Yuri Gagarin's first manned space flight, the president of the Soviet Academy of Sciences, Dr Anatoli P. Aleksandrov, spoke in a low key for such an occasion.

Aleksandrov's speech was little more than a justification of expenditure so far, and a defence of the proposition that the more that is spent on space, the greater the eventual benefit. This is not the first indication that Soviet space research may be running into financial difficulties. Earlier this year, the Soviet side had to make it clear to their French partners that if the two countries were to carry out a joint mission to Halley's comet, spending on their Venus mission of 1986 would have to be halved.

To demonstrate the priority being given to cost-effectiveness, Aleksandrov explained that three and a half years ago the cosmonauts aboard Salyut-4 were working on behalf of only 40 scientific and industrial bodies, whereas in the latest mission, Vladimir Kovalenko and Viktor Savinykh on Salyut-6 were providing data for some 400 organizations.

Naturally Aleksandrov did not discuss any military aspects of the Soviet space programme, although he did add to the abuse of the US space shuttle as a military vehicle. The press in the Soviet Union suggest that the US shuttle is primarily for launching laser weapons into space.

Soviet intentions on reusable launching systems remain unclear, however. Aleksandrov did not discuss any such plans, but Soviet cosmonaut Vitalii Sevastyanov stated in the Slovak daily *Pravda* that the Soviets were considering the construction of a shuttle. He claimed, though, that the present conventional methods used in Soviet space launches were more convenient than a shuttle for their programme based on large orbital stations designed for "peaceful purposes" and "suitable for a longer stay in orbit of scores of specialists".

There is speculation in the West, however, that at least one experimental Soviet shuttle has been launched — number 929 in the "Kosmos" unmanned satellite series.

Vera Rich

Anglo-German project Aurora held up

Red tape has already delayed the British half of an Anglo-German programme of auroral investigations for several months. Last week, one of the obstacles — agreement on the wording of a lease for land at a site in the north of Scotland — was surmounted. But a further six months delay is now likely, pending the installation of an electricity supply to the site.

The joint programme, known as SABRE, is for radar backscatter observations of the aurora from two sites — near Wick in Scotland and at Uppsala in Sweden. The two collaborating groups are led by Professor Tudor Jones at the University of Leicester and Professor I Axford at the Max Planck Institut für Aeronomie, Lindau. The British Science Research Council and the Max Planck Institut are supporting the experiments to the tune of about £200,000 each.

The programme is designed to complement a similar twin auroral radar, called STARE, operated from two sites in northern Scandinavia by the Lindau group. Observations from the Swedish site began last January, but delays in preparing the Scottish site have meant that spatially and temporally resolved observations have not yet been possible.

The Scottish site is one of four sites originally owned by the Ministry of Defence but now controlled by the Property Services Agency which deals with matters relating to public land. Most of the hold-up seems attributable to delays in reaching agreement on improving accommodation and connecting an electricity supply. The agency, which plans to sell the other three sites, has been concerned that the electricity supplies of each should be independent. At present, the supply to the site which the University of Leicester wants to lease is routed via a transformer situated elsewhere. Four options for installing a new supply, presented by the North of Scotland Hydroelectric Board, have been turned down as too costly.

Some blame the delays on the snail's pace at which the Property Services Agency works. After 18 months of turning the bureaucratic handle, an acceptable draft lease finally arrived at the University of Leicester only last week. But the problem of installing a new electricity supply remains. A mains cable supplying the site was apparently damaged a few years ago when a new road was built. Repairs involve laying new cables. The North of Scotland Hydroelectric Board estimates that the job could take six months and cost about £5,000. The agency has now handed over responsibility to the university.

If work cannot be speeded up, a temporary generator will have to be installed if experiments are to begin before winter.

Judy Redfearn

US nuclear power Cost disputed

Washington

Efforts to meet the safety problems created by nuclear power have already made nuclear energy considerably more expensive than electricity from modern coal-fired plants, even with the sophisticated anti-pollution equipment needed in coal-fired stations. And the gap is likely to increase at least until the end of the decade according to a report published in New York last week by an independent energy economist, Charles Komanoff.

The nuclear industry has reacted sceptically to Komanoff's prediction, claiming that he underestimates the productivity of nuclear power, and overestimates the productivity of coal generation. The Atomic Industry Forum, chief spokesman for the nuclear industry, issued a statement saying that the conclusions clash with those of other economists, and that "to predict cost trends for coal and nuclear in a period of fuel-price volatility and still-uncontrolled inflation seems highly dubious".

However, Komanoff, who last year gave evidence on nuclear power costs to the UK House of Commons Select Committee on Energy, is standing by his figures. He points out that similar scepticism greeted a prediction he made five years ago that the nuclear industry would be operating at only 55 per cent of capacity through to the end of the 1970s, a figure which has turned out close to the truth.

He also claims that the argument about coal being cheaper than nuclear power appears to be supported by figures published by the Atomic Industry Forum itself. In a report issued two months ago, the industry group estimated that electricity from the three nuclear plants which started operation in 1978 cost 2.5 cents per kilowatt hour to produce, compared with 2.0 cents for coal and 5.7 cents for oil.

Komanoff maintains that the more nuclear power has expanded, the more generic problems it has revealed, and the greater the effort required to prevent the number of nuclear incidents from increasing at the same rate. He says this is substantiated by the steady increase in the number of warnings of potential generic problems by the Nuclear Regulatory Commission during the past decade.

Komanoff bases his future projections on the cost of obtaining electricity from coal-fired plants by assuming that increasingly stringent controls will require the use of scrubbers to remove sulphur dioxide — devices that can consume up to 25 per cent of the capital costs of a new plant — and that the cost of coal will increase at a rate about 2 per cent more than the inflation rate. On this basis a coal plant will increase in capital cost from \$583 to \$794 per kilowatt hour of generating capacity in "constant" dollars. In

contrast, extrapolating on past trends in the rising costs of nuclear power plants due to the need to include increasingly stringent safety precautions, Komanoff predicts that the cost will rise from \$887 to \$1,374 per kilowatt hour of capacity.

The Atomic Industry Forum is looking closely at Komanoff's figures. Its own analysis, based on power plants coming into operation between 1970 and 1978, is that "nuclear electricity in 1979 continued to show a modest advantage in total generating cost compared with neighbouring coal units", and that nuclear power also compared favourably with coal in capacity factor. At the same time, the industry group admits that regulatory delays and public intervention in licensing procedures "run up nuclear costs significantly", it claims that there are approximately one dozen nuclear plants currently snarled up in bureaucratic delays which will cost US consumers as much as \$3,000 million in higher utility bills.

Whichever analysis of the relative costs of nuclear and coal is correct, however, both sides agree that immediate prospects for the US nuclear industry are bleak. Only 13 new nuclear-power plants have been ordered in the United States since 1975, and plans for 50 plants have been cancelled — many because of decreasing predictions of future energy needs.

On top of this, no new plants have been ordered in the past two years. The nuclear industry is hoping that President Reagan will make good his election promises of increased support, and is already providing him with suggestions as to how this might be achieved, from revamping some of the safety regulations which Komanoff claims to be at the root of the cost escalation, to proposals for federal financial aid for nuclear-plant construction.

Overhauling the regulatory apparatus, however, will not be easy. Only one of the five seats on the Nuclear Regulatory Commission is vacant, and two of the existing commissioners have been harsh critics of some of the industry's demands. In addition, Mr Reagan's rumoured choice for the chairmanship of the commission, former head of naval operations Admiral James L. Holloway, is reported to have turned down the offer, and with no clear indication of the direction in which it is meant to be moving, the commission is running at half speed.

David Dickson

Anti-viral drugs

Herpes on trial

Volunteers, 50 male and 50 female, with genital herpes simplex infections are being sought by the Infectious Diseases Unit at the University of Texas Health Science Center at Dallas to take part in clinical trials of the promising antiviral drug acyclovir (acycloguanosine). There is as yet no effective treatment for genital herpes, which is sexually transmitted and now

considered to be of epidemic proportions in the United States, where 300,000 new cases are reported each year. Each new patient becomes a carrier for life. Acyclovir has generated great enthusiasm at Burroughs Wellcome, its developers, as a real advance in treating the disease. One worry, though, is that viruses may acquire resistance.

Herpes simplex virus (HSV) can infect any part of the skin or mucous membrane. HSV Type 1 cause the familiar "cold sore" blisters on the lip. Genital herpes, caused by HSV Type 2, is a more severe condition and causes painful blisters in the genital area. In the Dallas trial the drug will be applied as an ointment over skin areas where patients feel a tingling, burning or itching sensation (a "prodrome") suggesting that a blister is about to develop. Acyclovir will be compared with placebo cream containing no active agent. If the drug succeeds in reducing the period of recurrences to one or two days, it should not only reduce the period of pain for the patient, but also reduce the capacity for passing on the disease to others.

Because viruses are parasites of the normal systems of the cell they infect, antiviral drugs tend also to act against the host cell. There are few points at which the life processes of the virus can be properly differentiated from those of the host, but acyclovir acts specifically against herpesvirus through one such reaction (*Nature* 272, 583, 1978). It is phosphorylated by the herpes-specified enzyme thymidine kinase, so that the active triphosphate derivative is present in much greater quantities in infected than in uninfected cells. In a sense, the virus thereby invites its own destruction. It remains to be seen whether acyclovir will prove active against even the dormant form of the virus. Herpes infection is characterized by the way in which all outward evidence of the infection can disappear, but the virus persists undetected in certain nerve cells.

Acyclovir is being used as an ointment in the Dallas study, but later tests will include systemic (for example intravenous) injections which could increase the range of infections against which the drug can be used. Already acyclovir has proved active as an eye ointment against herpes simplex corneal ulcers, and less conclusively against viral pneumonia.

The US National Institutes of Health are to fund trials of intravenous acyclovir in newborn babies with neonatal herpes, in comparison with adenosine arabinoside (vidarabine), and in cases of herpes encephalitis, in comparison with the adenoside of adenosine monophosphate. Neonatal herpes is a herpes simplex infection contracted from the infected mother during passage through the birth canal — if the virus reaches the brain it can cause death. Herpes encephalitis is caused by reactivation of the virus in the brain.

Charles Wenz

European Earth sciences Unity prevails

Strasbourg

Europe's Earth scientists may yet unite. A meeting on 13–16 April at the assembly of the Council of Europe saw the first public appearance of the European Union of Geosciences (EUG). At present, EUG consists of a founding committee and has the official status of a working party of the Parliamentary Assembly of the Council of Europe. Its aim is to provide an organization which encourages the exchange of ideas and information across the more traditional subject barriers that separate geologists from the geochemists, geophysicists and oceanographers. To that end, membership is open to any geoscientist, but officials of EUG are to be nationals of the member countries of the Council of Europe.

At present, EUG is run by a founding committee under Professor C. J. Allegre of the University of Paris, and its formal statutes are to remain provisional until approved at a future meeting. EUG intends to hold a regular meeting in the spring in Strasbourg every other year, its interdisciplinary scope is to be complemented by more specific topical conferences to be held between the more general meetings. The concept and format of EUG owe a lot to the success of the American Geophysical Union and its big annual spring and fall meetings, which have almost become a must for many European researchers. However, the scope is to be wider insofar as it is to encompass all Earth scientists, not only those in the geophysical community. In this way, it hopes to avoid rivalries and misunderstandings with the European Geophysical Society, which caters for the same scientific community as the American Geophysical Union.

Although the European Science Foundation (ESF) did not play a major part in the organization of the Strasbourg meeting, it appears that ESF is prepared to help set up and support a small permanent office for EUG in Strasbourg. Is this the beginning of ESF taking a more active interest in the Earth sciences, an area hitherto neglected by its working parties?

The European Parliament building was made available by the Council of Europe for this first EUG meeting. Although organized at relatively short notice, it nevertheless managed to attract more than 600 participants and enough presentations to run a full four-day programme grouped in 16 different sessions.

The abstracts from the first meeting appeared as the first issue of an ambitious new publication called *Terra Cognita*. EUG hopes to develop this into a quarterly journal which should serve as a forum for scientific information on research projects and activities as well as to promote the discussion and exchange of ideas within the Earthsciences community. Konrad Guettler

Out on a limb

Brussels

Dutch Socialist Member of the European Parliament, Annie Krouwel-Vlam, is trying to whip up support for a European Community directive on common rules for organ transplants. She is surprised that there are no rules regulating relations between organ banks and facilitating access for would-be recipients of new parts. Such measures would implant a greater awareness of the benefits of the European Community in the breasts of its citizens, she asserted.

Her suggestion has been passed to the Community's organ banks and the European Commission. So international banking could soon take on a new meaning.

Jasper Becker

Interferon business

Trials ahead

Rotterdam

That interferon is big business can only have escaped the notice of those totally occupied for the past two years in preventing the pollution of space by small plastic tiles. That it continues to be big business was evident from the number of companies represented last week (19–24 April) at the interferon meeting organized by TNO, the Netherlands organization for applied scientific research.

Half of the British participants were from Beechams, Celltech, Fisons, ICI, G. D. Searle and Wellcome, with about the same proportion of commercial people among the West Germans. The large United States contingent included representatives of Cetus, Du Pont, Enzo Biochem, Electro Nucleonics, Genentech, Hoffman-La Roche, Hydron, Meloy, Sepetex, Schering and Shell. Not a slide went unphotographed nor a talk unrecorded by one or more commercially interested party.

Many of these companies already had a declared interest in interferon but some were new to the game. ICI let it be known that it has cloned an interferon gene from lymphoblastoid cells in collaboration with Dr E. de Maeyer's group at the Institut Curie in Orsay. ICI says that this is just an exercise in cloning, but with the setback in the fortunes of the company earlier in the year (*Nature* 12 March), there must be thoughts of trying to cash in on clones.

There is little doubt that the demand for highly purified interferon is growing, but the growth can be fitful. Wellcome, for example, recently claimed that supply had outstripped demand for its alpha-interferon (from white blood cells). That situation could easily be reversed if the current clinical trials of Wellcome's interferon show promise. The interim results, reported in Rotterdam, of several relatively large trials of a variety of different alpha-

interferons suggest that it has a tantalizing degree of activity against a broad spectrum of viral diseases and tumours. But activity is not enough, or consistent enough, in most diseases to give a final verdict without more trials. Also, as genetically-manipulated bacteria start to yield sufficient amounts of the ten or so subtypes of alpha-interferon, the permutations of subtypes and diseases becomes huge.

Meanwhile, large-scale trials of beta-interferon (from fibroblasts) lag slightly behind. The largest has yet to start. Financed and organized by the National Institutes of Health (NIH), the trial will use 50,000 million units of beta-interferon, enough for several hundred patients. The interferon is being supplied by Flow Laboratories Inc, which won the \$2 million contract a year ago. First deliveries were due a few weeks ago, but NIH appear to be in no hurry. This is lucky for Flow Laboratories, whose own production has not been going smoothly. Fortunately, they have a subcontract with the West Germany company of Dr Rentschler Arzneimittel GmbH which has continued to amass beta-interferon made by its own, less advanced, techniques.

The next big contract, also for NIH, will be for gamma-interferon (from cells of the immune system). Far less is known, at least publicly, about this type of interferon, but Biogen and Genentech are rumoured to be on the verge of cloning the relevant genes.

Other commercial interests centre on monoclonal antibodies against the interferons. Several new monoclonals against either alpha or beta-interferons were announced in Rotterdam, but only the original monoclonal (see *Nature* 285, 446, 1980) is as yet commercially available. The sellers are the British company Celltech Limited, so far its only product. It will be surprising if the Celltech catalogue does not double soon.

Peter Newmark

Dioxin hazards

Secrecy at Coalite

Secrecy about the medical consequences to workers exposed to dioxin continues at the British company Coalite and Chemical Products Limited. Documents now to hand show that Coalite will not agree to the further medical investigation of workpeople if the physicians concerned insist that the results are eventually published.

Coalite's shyness is not unprecedented. Last year, the company withheld information on an epidemiological survey of workers exposed to dioxin (2,3,7,8-tetrachlorodibenzodioxin) at its Bolsover (Derbyshire) plant in 1968-71 (see *Nature*, 6 March 1980). The exposure followed an explosion in a vessel used for the manufacture of 2,4,5-trichlorophenol and the workers affected by dioxin developed the skin disease chloracne.

The fresh trouble which has arisen at Coalite results from the need for more

detailed investigations of individual workers to make up for the deficiencies of the epidemiological survey of 1977-78. That involved only 41 of the 90 workers known to have been exposed, but revealed (almost a decade after the event) some abnormalities of blood chemistry and immune function — but none of the expected chromosomal abnormalities in circulating lymphocytes.

The news that Coalite was unwilling to disclose information about this survey served to alert the statutory Employment Medical Advisory Service of the Health and Safety Executive to the existence of such data, which was disclosed on a confidential basis after three weeks. The service has also persuaded Coalite that its medical adviser, Dr George May, should publish some of the results.

The employment service has in the meantime been uncomplimentary about the survey which, it says, is deficient in its failure to follow up past employees and in the inadequate matching of the control populations. The survey covered 41 workers known to have been exposed to dioxin, 54 who might have been exposed and 31 intended as a control group but drawn for convenience from senior office, laboratory and works staff, most of whom were being investigated for blood lipids at the time.

The 1977-78 survey showed blood-lipid disorders, with elevated concentrations of serum cholesterol and triglycerides, and depressed levels of high-density lipoprotein. The enzyme γ -glutamyl transpeptidase, diagnostic of liver function, was abnormally high in the exposed group. On the other hand, levels of two immunoglobulins (IgD and IgM) were depressed in the exposed group, suggesting impairment of immune as well as liver function.

The significance of these findings is far from clear, with the consensus among physicians in the field that further investigations are needed. They argue that the persistence of the phenomena uncovered by the earlier study should be confirmed — but also that further surveys should be more carefully controlled.

Dr George May, Coalite's company doctor, confirms that those workers included in the original survey have since been offered a second medical examination, but that "not everybody availed themselves of the opportunity". In the event, 29 of the original sample of 41 workers were re-examined, but measurements of immunoglobulin were not made.

There are no plans, however, for further investigations of the Coalite workers, according to Dr George Sorrie, deputy director of the Employment Medical Advisory Service, who says that his service has not been presented with any "realistic and useful" proposals for a long-term assessment of the health of the Coalite workers. The reassessment of the state of health of dioxin-exposed workers at

Dioxin a sarcoma risk

Reassessing clinical data is not the only reason for monitoring the health of workers exposed to dioxin. Recent letters in *The Lancet* (P A Honchor and W E Halperin, i, 268, 31 January 1980, and R R Cook, i, 618, 14 March 1980) highlight another reason.

The authors of the letters point out that in four industry-sponsored mortality studies of dioxin-exposed workers in the United States, 105 deaths were recorded. In four of these cases, death was caused by soft tissue sarcomas. These are rare forms of cancer and for most the aetiologies are unknown.

Soft tissue sarcomas have also been identified in another cohort of workers considered to have been exposed to dioxin. According to two Swedish epidemiologists, Dr Lennart Hardell and Anita Sandstrom of the Centre of Oncology at the University of Umea, exposure to the dioxin contaminated herbicide 2,4,5-T (2,4,5-trichlorophenoxyacetic acid) or chlorinated phenols 6 to 20 years previously could be responsible for the sixfold greater incidence of soft tissue sarcomas recorded in a survey of Swedish forestry workers (*British Journal of Cancer* 39, 711, 1979).

Alastair Hay

Coalite is thus far from complete. One clinician describes the re-examination of the 29 workers as a "totally useless piece of work" which cannot be expected to yield any meaningful results.

Coalite's managing director, Mr Charles Needham, has been approached by several clinicians prepared to carry out further investigations. Coalite's reluctance to agree to publication of the results from any future comprehensive medical screen of its workers has, however, forced at least one clinician to abandon his proposal.

Mr Needham, described by his secretary as solely responsible for press relations, has not been available for comment. One consequence of criticisms of the 1977-78 survey, and of Coalite's continued insistence on secrecy, is that the financial sponsor of the survey (an independent non-governmental source) will be unwilling to provide further support.

As the law stands, Coalite may have the last word. Hitherto, the company has been able to exploit an ambiguity in the 1974 Health and Safety at Work Act when deciding whether or not to release medical information on its workforce (see *Nature* 6 March 1980, p 2). The routine powers of the Health and Safety Executive to demand medical records of workers likely to have been affected by a product lapse when manufacture stops. Although Section 27 of the act allows the executive to disclose whatever information it requires (see *Nature* 1 May 1980, p 4), epidemiologists at the executive consider that a test case is required to clarify the law.

Alastair Hay

CORRESPONDENCE

Majority verdict

SIR — In a recent communication to *Nature* G G Simpson writes about a small group of cladists at the American Museum of Natural History that is not representative of the staff as a whole (*Nature* 26 March, p 286). In his view a majority of the staff rejects cladistic or Hennigian procedures. There are 32 professional zoological systematists on the staff here, not including emeriti or honorary staff appointments, and 26 of these use cladistic methods in their systematic work. The small, unrepresentative group referred to by Simpson therefore amounts to 81 per cent of the relevant staff. On the recommendation of three scientific departments, the Council of the Scientific Staff, and the Awards Committee, the trustees of the museum in 1975 gave Willi Hennig its Gold Medal for distinguished contributions to science.

'I was there'

SIR — Your account (*Nature* April 9, p 435) of a lecture I delivered "at the Rockefeller University in New York last week" raises in me the strong suspicion that your reporter did not hear what I said. This impression is strengthened by the fact that the lecture he reports was actually given in the Cornell University Medical Center. J L GOWANS
*Medical Research Council,
London W1, UK*

Dr Gowans' suspicion is unfounded. Our reporter indeed heard what was said and reported accurately that part of Dr Gowans' talk concerned with the applicability of the Rothchild principle to the financing of medical research in Britain. The Cornell University Medical Center is on the other side of York Avenue in Manhattan from the Rockefeller University, which had advertised the meeting at which Dr Gowans spoke. The two institutions run many joint seminar programmes, but are of course organisationally distinct. — Editor, *Nature*

Evolution's Waterloo

SIR — While no sensible person could disagree with your position on the "theory of evolution" (*Nature*, 12 March, p 75) I think your arguments are unnecessarily weakened by the sloppy use of words in multiple meanings, enabling your opponents to confuse the issue.

The phrase "theory of evolution" for example, is used in at least two quite different meanings. At one time it means "a record of events in the history of the Earth", at another it means "an explanation of the underlying causes of these events".

The term "metaphysical theory" is another example of this abuse. Popper notwithstanding, a metaphysical theory, *sensu stricto*, is a theory which cannot be verified (or

falsified) either now, or ever or anywhere, say the proposition "God exists". The record of historical events, say the proposition "Napoleon lost the battle of Waterloo" is not a metaphysical theory. Although the event cannot be rerun, it certainly can be verified in many different ways. Therefore the "theory of evolution" in its first meaning cannot be called metaphysical, technically or otherwise. An explanation of why Napoleon lost the battle of Waterloo, on the other hand, may or may not be metaphysical, according to whether it is based on verifiable facts or not. An explanation based on the intervention of an army of angels could be called metaphysical, one based on the superiority of the British and Prussian rifles may or may not be true, but it certainly is not metaphysical. The same reasoning holds for the "theory of evolution" in its second meaning.

*Administration de l'Industrie, S V VAECK
Brussels, Belgium*

SIR — As an American "cladist" and evolutionist concerned with the health of both disciplines and the public reaction to them, I feel that some discussion of the issues raised in *Nature* is warranted.

The issue of creation versus evolution entails two points, neither of which was mentioned in sufficient detail for the public readers of *Nature* properly to understand. First, the real controversy is over whether or not the phenomenon of evolution occurs. It does not concern whether Darwin or anyone else was correct about the mechanisms behind the phenomenon. To imply that a refutation of Darwinism or neo-Darwinism constitutes a refutation of evolution is like implying that a refutation of Newtonism is a refutation of gravitational attraction. Both conclusions would be misconceived. Second, the issue of creationism versus evolution certainly does not rest on whether Karl Popper's particular philosophy of science renders both creationist myths and Darwinian conjectures "untestable." There is a higher principle to resolve this issue.

Science is a discipline of open-minded inquiry which seeks to provide explanations about the world without invoking the supernatural. Creationism as practised by fundamentalist Christians is a close-minded doctrine built around an ultimate source of truth, the Bible. Creationism is dedicated to the proposition that the only explanations about "origins" are the supernatural explanations set forth in their ultimate source of truth. Thus "scientific" creationism, by any standard of rational scientific philosophy, is not science nor can it ever be science. Karl Popper is quite aware of this and has said so in *Conjectures and Refutations*.

Another issue concerns what is being called "cladistics." Scientists who fall under this label have diverse views about the proper relationship between "cladistics" and evolution. As one "out-and-out cladist" I cannot imagine something less interesting than a branching diagram (cladogram) without an evolutionary interpretation. Indeed, I cannot imagine beginning a study of biogeography without such an interpretation. I will even claim that an assumption of descent with modification is necessary to do such analyses. I base my claim on two points.

First, I have never seen a natural hierarchy

that was not due to historical descent in the larger sense of the phrase. This includes natural hierarchies in both the organic and inorganic worlds. Examples of natural hierarchies in the organic world are, of course, phylogenies of both organisms and languages, and the hierarchy of ontogeny of individual multicellular organisms. The only example of a natural hierarchy in the inorganic world that I know of is the hierarchy that continents display through descent from common "ancestral" continents. We observe the unfolding of ontogeny, we have detailed histories for the evolution of languages, we have a very good mechanism for the drifting of continents. Are we to think that the only other example of a natural hierarchy, the branching relationships between species, is different in kind from the other three?

Second, the only alternative to the evolutionary interpretation is the assumption of a logical creator who made each species (or group of species, or language, or continent) to look as if it evolved. As I wish to practise science rather than theological metaphysics, I make the assumption of evolution. If I wished to practise theological metaphysics, I would certainly not conceive of a logical creator who was, at the same time, tricky enough to make things look as if they evolved when they did not. I make the assumption of evolution without letting my hypotheses of evolutionary relationships (cladograms to my mind) be dictated by particular theories such as neo-Darwinism. If I let neo-Darwinism dictate *a priori* what relationships were possible then I would be no better than the fundamentalists who let the Bible dictate to them what is possible.

No to sociobiology

SIR — The recent controversy on genes and racialism (*Nature* 22 January, 12, 19, 26 February) may have some relevance to caste system in India, since it has now assumed a great political significance and is creating social tensions. Although castes are manmade (all Hindus are born unequal!), and the system is nowhere near as old as the human race, yet attempts are often made to establish a biological basis of castism in line with the insect societies. Wilson (in *Sociobiology*) has refuted any genetical basis for caste system, yet willy-nilly, theoretical biology has become a convenient and manipulative tool to disdain or support such social practices.

The problem will become more complex and acute if attempts are continued to biologize every social attribute, be it racialism, castism or nazism. Biologization may be well-intentioned, and it may well prove that some of our beliefs are wrong and unscientific, yet by this process it may generate unnecessary, avoidable controversies and social conflicts. Surely, without biologizing, one can distinguish between races and racialism and between castes and castism. One may dispute or not give a damn if the human race is united or divided, but one can surely condemn racialism or castism without looking for biological evidence or defending the theory of kin selection. Let us keep sociology and biology apart.

NEWS AND VIEWS

Springcleaning ribosomal DNA: a model for multigene evolution?

from Gabriel Dover and Enrico Coen

THE nuclear DNA of higher organisms is subject to such a diversity of sequence rearrangements that one might wonder how developmental or evolutionary stability is maintained. The variety of rearrangements, no doubt arising as errors in the regular processes of DNA replication and recombination, gives rise to seemingly randomly distributed families of multiple-copy sequences. A major unresolved question concerns the biological and evolutionary consequences of these mutational processes. One particular family of sequences that might provide the first insights into the rates at which different mutational mechanisms progress and of their possible phenotypic effects is composed of tandem head-to-tail arrays of ribosomal RNA genes (rDNA). From the data reported in this issue of *Nature*, p 749, by H Roija, J R Miller, L C Woods and D M Glover, and elsewhere²⁻⁵ it is now possible to observe in one family of repetitive sequences most, if not all, the phenomena usually depicted separately in different families.

The 18S, 5.8S and 28S RNA moieties of eukaryote ribosomes are co-transcribed from a unit of contiguous genes separated by internal and external transcribed spacers (ITS and ETS in the figure). Units are separated by non-transcribed spacers (NTS), in arrays that are located at the nucleolar organizers (NO). An exhaustive *variorum* account of the organization of rDNA and other multiple gene families has recently been compiled by Long and David⁶.

Since the pioneering studies of D D Brown, P K Wellauer, R H Reeder and I David into rDNA variation in species of *Xenopus*, it has become apparent that this family of repeats has been subjected to a new type of evolutionary force termed horizontal^{7,8} or concerted² evolution. This term is used to describe extensive sequence homology of NT spacers within a species

even though there is very little homology between spacers of related species. The mechanism responsible for concerted evolution of copies of a sequence within and between individuals should take into account the striking interspecific homology of the genes with which the spacers are regularly interspersed — for example^{3,9}, there is 93 per cent homology within 200 base pairs of the 28S gene of an insect³, an amphibian⁹ and a ciliate protozoan¹⁰ — and should result in rapid 'horizontal' spread of each new spacer variant to all rDNA units of all individuals of a species. Alternatively, it is conceivable, although unlikely, that both the rDNA arrays and populations go through drastic reductions in number followed by the establishment of new arrays from a few founder units. The recent analysis of sequence variation of rDNA in a variety of organisms, in particular in species of *Drosophila*, reveals several overlapping levels of evolutionary change that throw some light on the mechanism of concerted evolution and the complex progression of rDNA in general.

In *Drosophila melanogaster* there are two clusters of rDNA situated on the X and Y chromosomes. An interesting additional feature is that 60 per cent of the 28S genes of the X chromosome contain an insertion (INS-type I). Another non-homologous type II INS is present in 15 per cent of the 28S genes of both chromosomes. Although insertion sequences are by no means a universal feature of nuclear 28S genes (they are confined so far to the higher diptera of metazoan animals and to ciliate protozoa), they have been shown to contain sufficient residual interspecific homology to suggest that they are of ancient origin and arose before the divergence of the dipteran

suborder Cyclorrhapha into the calyptrates (such as the house-fly) and acalyptrates (such as *Drosophila*) approximately 65 Myr ago¹¹. Bearing in mind their age it is clear that if complete rDNA arrays are subjected to a concerted 'spring-clean', then the INS⁺ units are either selectively maintained or periodically re-inserted into newly amplified units. For the latter they would require a degree of mobility.

The data of Glover and Rae and their colleagues^{1,3} on the nucleotides surrounding INS elements in *Drosophila* elucidate this question of mobility. In *Drosophila virilis* there is a 14-base pair duplication of a 28S gene sequence that flanks the insert. This same sequence is present only once in INS⁻ units. The generation of a host sequence duplication (usually of 5–9 base pairs) upon insertion of an extraneous sequence is a common feature of mobile elements in *Drosophila* and yeast^{12,13}. In *D. melanogaster* the type I INS is flanked on its right by this same sequence and on the left there is a 9-base pair deletion in the 28S gene. The two inserts clearly slot into identical positions in the two species suggesting a requirement for some sequence homology between host and insert that is analogous to the integration of λ phages into *Escherichia coli*. These data underline the possibility of mobility of INS elements. It is unlikely that there are any fundamental differences between the units that receive INS and those that do not. For example, Long, Rebert and David¹⁴ find no differences between INS⁺ and INS⁻ units in 470 nucleotides around the transcription initiation sites and in the sensitivity to DNase I of the chromatin of genes, spacers and inserts. Is there, then, a limiting supply

Gabriel Dover and Enrico Coen are in the Department of Genetics, University of Cambridge

of INS elements to re-occupy the 60 per cent of X chromosome 28S genes with type I and the 15 per cent of X and Y 28S genes with type II, or are the numbers selectively constrained? Interestingly, extra copies of type I sequences have been located outside of the NOs in both *D melanogaster*⁴ and *D virilis*³ that are situated for the most part in the centromeric heterochromatin in *D melanogaster*⁵. However, type I INS units in the heterochromatin are each flanked by the same 28S gene segments that flank type I INS in the 28S gene¹, suggesting a transposition of INS with its flanking sequences from the NO to the heterochromatin and not vice versa.

The phenomenon of concerted rDNA evolution in *Drosophila* species has only recently come to light. Electron microscope observations on the extent of heteroduplex matching of interspecific NT spacers of sibling species of the *D melanogaster* species subgroup initially underscored, at this level of resolution, the conservation, not the dissimilarities, in spacers between the species¹⁵. However, our analysis of the distribution of restriction sites and sequence homologies of NTS, ITS and INS elements of the species nevertheless shows that all these components are divergent between species and yet have evolved in concert within each species to the extent that a complete replacement of one sequence variant by another has occurred in both X and Y NOs¹⁶. Similarly, the NTS sequences of two more distantly related species, *D melanogaster* and *D hydei*, have been found not to be the same¹⁷.

Although evidence for the precise mechanism responsible for within-species homogeneity is not available, there are observations that strongly hint at one possible cause. A variety of studies have shown that an heterogeneity in length and an internal repetition within NT spacers are common features of multiple-copy genes (see refs 7 and 18 for reviews). For example, the lengths of NT spacers both within and between sibling species of *D melanogaster* often differ by multiples of 250 base pairs¹⁶ which is the periodicity of the *AluI* repetition in the NTS of *D melanogaster* (see figure). It has been suggested^{7,8} that a process of unequal exchange within NT spacers, in which the inequality is of the same periodicity as the internal repetition, would generate the observed differences. Given such a mechanism plus the ability of sequences of DNA to transpose or be exchanged between chromosomes, it is possible to offer some explanation for the complete horizontal replacement, at several different levels, of the rDNA within and between individuals in one group of species.

First, within the NO of one chromosome it is possible to view the replacement of repeats, one variant by another, as an outcome of a continuous process of amplification and elimination of sequences (by unequal exchange) in a stochastic

manner. At the lowest level there would be the replacement of units of the internal repetition within the NTS, for example, in *D melanogaster* a replacement by a variant repeat (containing an *AluI* site) has taken place in an array of 250-base pair repeats (lacking the *AluI* site) that is probably common to the NT spacers of the sibling subgroup¹⁶. An analogous 250-base pair periodicity has been detected in the NTS of *D hydei*¹⁷. In addition, unequal exchange within the internal repetition would also give rise to the 250-base pair length heterogeneity described above. At a higher, level unequal exchange involving complete rDNA units would lead to the replacement of complete arrays of NT spacers with their variant internal repeats in any one NO.

The second step in the process of sequence encroachment would be the establishment of the same spacer variant in all NOs of a karyotype. N. Arnheim and his colleagues report the complete distribution of spacer variants to several NOs within any one species of primate², analogous to the distribution of *AluI* variants to the X and Y NOs of *D melanogaster*¹⁶. Such a mobility between chromosomes could be either a direct transposition or dependent on both meiotic (homologous) and mitotic (non-homologous) chromosome exchanges. Finally, and importantly, if the processes of unequal exchange and interchromosome spreading are rapid, then a variant will be driven throughout a population of sexually reproducing individuals the last stage of concerted evolution. The absence of much rDNA sequence polymorphism, as distinct from length heterogeneity, within species suggests that the mutation rate producing new variants might be low relative to the rates at which they displace and spread both within and between individuals.

Against such a background of periodic replacement of rDNA units, in *Drosophila*, the exclusion of specific INSs from the NOs of the Y chromosomes of *D melanogaster*⁶ and *D hydei*⁷ suggests that insertion is a separate and independent stage in the overall evolution of the rDNA clusters.

The role of selection in the evolution of rDNA is much harder to gauge. There is probably a selective constraint on the number of 28S genes that can accept an insertion given the small deletion¹ (Glover

op cit) and the absence of transcription of INS⁺ genes in somatic tissues of *D melanogaster*^{4,19} although the role of selection is ambiguous in strains of *Tetrahymena pigmentosa* which differ by the total absence or presence of insertions throughout the 28S genes¹¹. There might also be a selective constraint that restricts the length heterogeneity of NTSs to within the defined lengths observed between sibling species of *Drosophila*¹⁶ and within individually characterized X and Y NOs of *D melanogaster*^{4,16,20,21}. This might ensure the correct phasing of nucleosomes vis-à-vis the transcription initiation sites of the repeats. An interesting regularity in nucleosome phasing with this property has recently been revealed in multiple-copy families of histone and ribosome genes in *D melanogaster*²² and in 5S RNA arrays of *X laevis*²³.

One final consideration concerns the generality of the phenomenon of concerted evolution and repeat unit replacement in eukaryote genomes. It is known that repeated sequences are undergoing recurrent rounds of amplification and that on occasion a variant member becomes the fortuitous unit of amplification leading to the establishment of an homogeneous but variant array (segment) (see ref. 24 for references). Such polymorphic segments might represent a state of transition during replacement. Segmental variants and concerted replacement have been observed in tandem arrays of satellite DNAs, histones, immunoglobulins and globins, in addition to rDNA. Recently, evidence for concerted replacement has been found in a set of repeats that are dispersed throughout the genomes of different rodent species²⁵. This might result from a progressive 'gene conversion' of one interspersed repeat by another (rather than unequal exchange) along the lines described by Scherer and Davis in yeast²⁶.

The genomic consequences of sequence replacement, mobility and interchromosome spread, occurring simultaneously, for example, in the rDNA repeats, are clear: the rapid establishment of a group of genomes (species) that are uniquely identified by many shared homogeneous families of sequences. The biological consequences of the accidental fixation of multiple genomic dissimilarities between groups are endless. □

Continental margin processes

from David G Roberts

OVER the last decade research on continental margins has been greatly stimulated by the need to assess the hydrocarbon potential of the largely unexplored margin areas and to develop a thorough geological and geophysical understanding of the transition across the fundamental crustal boundaries defined by passive and active margins. The recent Hedberg Conference* was the third to review continental margins since the original Penrose Conference of 1972 (see *The Geology of Continental Margins* Springer Verlag, 1975).

Results obtained from seismic exploration allied to the International Phase of Ocean Drilling (IPOD) were reviewed by A W Bally (Shell Oil, USA). Specific problems of passive margins revealed by the different structural styles of the north Biscay and eastern North American margins include the mechanism and amount of stretching during rifting and its effect on the subsequent history and thermal subsidence. In the case of active shear and convergent margins the structural implications of brittle-ductile boundaries in the lower crust have yet to be fully understood as has the role of crustal extension in an active margin setting. Bally urged full documentation of the palaeontological data base used to erect the global sea-level curves of Vail *et al* (*Mem Am Ass petrol Geol* 26; 44, 1981) and suggested changes in the subsidence rate of margins due to global sea-level variations as an alternative mechanism.

Convergent margins were reviewed by Von Huene (USGS, Menlo Park). IPOD drilling and associated seismic surveys have revealed evidence of uplift and tectonic erosion that have radical implications for mechanisms of thrusting and subduction. Subduction erosion or underplating has been proposed to account for tectonic erosion off Central America while uplift on the Japanese active margin may result from development of a normal, that is, more elevated geothermal gradient during periods of inactive subduction. Recession of the continental edge by as much as 60 km from the trenches may now be accounted for by dewatering and temperature-controlled 'clay' mineral transformations with associated faulting in response to weak shear stress conditions in the accreting sediments.

Other active margins discussed included the Nankai Trough off Japan (Aoki, Japan Petroleum) and the Makran margin where uplift related to convergence is about

1.5–2 km per million years (White, University of Cambridge). Examples from the Caribbean included the margins of Venezuela and Hispaniola where studies of seismic reflection profiles offshore have been integrated with a field study of the exposed parts of the active margin onshore (Biju-Duval, IFP, France). Along the Indonesian Arc (Curry, Scripps Institution) variations in structural style are reflected in the development of strike-slip faults and spreading back arc basins in turn related to the direction of convergence. Episodicity in the geological history of the exposed parts of the Arc may be more apparent than real and is perhaps caused by changes in plate convergence. Uplift and subsidence of part of the Aleutian Arc were also documented by Scholl (USGS, Menlo Park).

The Caledonian–Appalachian orogenic belt was the subject of several interesting interpretative comparisons with the marine results. Leggett (Imperial College, London) demonstrated the particularly striking resemblance between the Southern Uplands of Scotland, the Makran and the Middle American Trench while McKerrow (University of Oxford) reviewed the history of the northwestern edge of the Iapetus Ocean. Evidence of very large-scale tectonic transport along convergent margins was documented from California and the Appalachian belt. 'Suspect' terranes in California show 30–40° of rotation and transport of Upper Cretaceous rocks by as much as 3,000 km (Howell, USGS, Menlo Park). COCORP results in Appalachia also demonstrate thrusting of several hundred kilometres along the Blue Ridge thrust and have wider implications in interpreting autochthonous terranes in the Caledonide–Appalachian belt.

The session on passive margin evolution included reports from all over the world. Grachev (Institute Physics of the Earth, USSR) reviewed the Moma rift — the onshore continuation in Siberia of the spreading Gakkel Ridge of the Arctic Ocean. Nunns (Durham, UK) discussed the evolution of the Norwegian Sea and the Jan Mayen microcontinent. The structure of the entire Southwest African margin from the Walvis Ridge to Capetown was presented by Gerard (SOEKOR, South Africa) using seismic reflection and commercial results. This margin, like the Voring Plateau, East Greenland and some other margins, is characterized by a thick sequence of oceanward dipping reflectors close to the continent–ocean boundary. Drilling suggests that these reflections may be basalts. Association of supposedly oceanic magnetic anomalies with

continental crust on this margin questions their use in defining the continent–ocean transition. The Congo–Cabinda area further north is a classical area of rift tectonics where the entire transition from the pre-rift phase through rifting, initiated in the late Jurassic, to the Albian post-rift and the important role of halokines is well documented from seismic and drilling results (Cochran *et al* Gulf Oil, USA).

Off eastern North America, improved seismic data and the results of recent IPOD legs have shed new light on the evolution of the margins. In the Straits of Florida (Buller and Schwab, UTMSI) drilling on partly exposed tilted blocks has cored gneisses and phyllites. Careful analysis of refraction (Ibrahim and Uchupi, WHOI) and gravity and magnetic data (Hall, Gulf Oil) from the Gulf of Mexico suggest rifting and spreading formed a rhomboidal oceanic in early Jurassic time. Independent evidence for early Jurassic opening of the western North Atlantic has been given by the results of DSDP hole H534 which cored basement of Callovian age east of the Blake Escarpment (Sheridan, Gradstein *et al*, University of Delaware). In the nearby Carolina Trough, the East Coast magnetic anomaly is interpreted as an edge effect associated with the continent–ocean boundary by Hutchinson *et al* (USGS–WHOI) who also find no evidence of a basement ridge along the boundary. They propose a model of rapid stretching and subsidence to account for a zone of attenuated continental crust landwards of the boundary. Present growth faulting on this margin is apparently related to tectonically controlled halokinesis (Dillon, USGS, WHOI).

Models of stretching and subsidence provided one of the main points of formal and informal discussion. McKenzie (*Earth planet Sci Lett* 40, 25, 1978) originally proposed a simple model of lithospheric stretching and applications of this model were discussed by several speakers. Sobolev and Artemjev (Institute Physics of the Earth, USSR) discussed rifting and stretching in terms of phase transitions within the mantle. Variations in the width of passive margins may be related to eclogitization. Keen *et al* (Bedford Institute, Canada) analysed the development of sedimentary basins off North America in terms of the McKenzie model, models of uniform extension with melt segregation and of depth-dependent extension requiring rheological zonation within the lithosphere. They compared calculated with observed gravity, stratigraphy, mantle depth and thermal history data and concluded that the depth-dependent extension model gave the best fit. A rather different view was proposed by Sibuet and Le Pichon whose

*The Hedberg Conference was held from January 12 to 16, 1981 and was convened to honour Hollis D. Hedberg, Professor of Geology at Princeton and former chief geologist of Gulf Oil. The meeting was sponsored by the American Association of Petroleum Geologists.

David G Roberts is a Principal Scientific Officer at the Institute of Oceanographic Sciences, UK.

calculations of the crustal extension in Biscay were consistent with the uniform stretching model of McKenzie and could be applied to other areas. Chenet *et al* (IFP, Paris, France) also calculated the extension for the north margin of Biscay and Galicia Bank and calculated that a two-layer model best fitted the data although a mass balance problem remained in the lower crust. Slater *et al* (MIT) reviewed subsidence of the Georges Bank in terms of the McKenzie model and discussed possible hydrocarbon potential in terms of the thermal history. A two-layer finite element crustal model used to model the formation of outer highs by Vierbuchen and George (Exon, Houston) included variables such as the temperature at the base of the lithosphere and time-dependent creep. Watts (Lamont-Doherty, New York, USA) reviewed the roles of eustasy, flexural strength, diagenesis, stretching and cooling in margin subsidence, concluding that at least off North America the paucity of well data and the unknown thickness of syn-rift sediments do not easily allow test of McKenzie's model.

Sedimentary processes in many continental margin environments were documented using a variety of techniques. Coumes (SNPA, Pau, France) examined the depositional history of the Cap Ferret Fan, south-west Biscay using Seabeam and high-resolution seismic data linked to cores. A wider view of continental margin sedimentary processes was given by Roberts (IOS, UK) from the results of long-range sonar (GLORIA) surveys. Complete sonar mosaics of entire continental margins are giving a needed overview of the role of downslope and slope sediment movement in determining facies distribution. The role of slope parallel and downslope sediment transport in the development of the lower continental rise off the eastern USA was documented using seismic profiles (Laine and Tucholke, WHOI). A detailed study of the McKenzie River delta was presented by Cole (Gulf, Canada) who recognized five deltaic cycles in the delta's development. Bouma (USGS, Corpus Christi) discussed the influence of halokinesis on upper slope sedimentation in the Gulf of Mexico.

The maturity and characteristics of organic matter on continental margins was appropriately discussed in the final session. Arthur (USGS, Denver) discussed the role of Mesozoic-Cenozoic anoxic events determining the production and presentation of organic matter along the slope and rise. Accumulations are episodic and themselves variable in organic matter and type. A detailed geochemical study of Cretaceous organic matter by Katz (Texaco, USA) showed differences between the North and South Atlantic Oceans. The North Atlantic organic matter is predominantly of terrestrial origin and is likely to yield gas compared with the oil potential of the marine organic matter in the South Atlantic Ocean. □

Solar physics at Taos

from R. Rosner

THE second major presentation of results from the Solar Maximum Mission (SMM) satellite, which recently met an untimely failure in its pointing system after approximately six months of active operation, provided the focal point at the winter meeting of the American Astronomical Society's Solar Physics Division*. This gave the solar community an excellent overview of both the current status and the likely scientific impact of the SMM venture. Several other major results not associated with the SMM programme were also discussed.

One of the first new results reported concerns periodic fluctuations in hard (≥ 20 keV) X-ray emission from solar flares. Such fluctuations have been observed by both the SMM Hard X-Ray Burst Spectrometer (HXRBS), reported by Kiplinger (Goddard Space Flight Center), and an X-ray spectrometer on board the ISEE-3 spacecraft (Kane, UC Berkeley), who also reported corresponding quasi-periodic variations in microwave radio bursts. The typical pulse period is ~ 8 s, on a coherence time scale of the order of several minutes. Several explanations were offered for these observations, one plausible model proposed by Morrison and Ionson (Goddard) considers the flaring 'loop' structure as a lumped resonant circuit whose solutions on short time scales successfully predict oscillatory behaviour with periods of the order of seconds.

Detailed flare plasma diagnostics have been considerably advanced by SMM observations. High-quality observational evidence for both systematic flows and turbulent velocities were reported by the Ultraviolet Spectrometer and Polarimeter (UVSP) and X-Ray Polychromator (XRP) experiment teams, for example, turbulent velocities (as measured by broadening of lines due to high ionization states of calcium and iron) were shown to attain values up to ~ 100 km s⁻¹ during flares. Data from these two instruments and from the HXRBS have been assembled by Frost, Orwig, Poland and Shine (Goddard) who reported evidence that considerable hard X-ray flare emission originates from the vicinity of flare loop footpoints. These data, together with high-resolution Very Large Array (VLA) observations (Kundu, University of Maryland, and collaborators), strongly support the view that a non-thermal component is present in the electron velocity distribution and is responsible for

the footpoint hard X-ray emission. Yet further evidence for non-thermal processes comes from the Gamma-Ray Spectrometer (GRS) Forrest (University of New Hampshire), Ramaty (Goddard) and collaborators showed spectra which clearly indicated line emission at, for example, 2.2 MeV (attributable to neutron capture by protons) and 0.51 MeV (corresponding to the well known e^-e^+ annihilation line), and demonstrated convincingly that both ions and electrons must be accelerated impulsively (and episodically) during a flare. On similar time scales, the detailed temporal variation of the 2.2-MeV line flux was shown to follow the hard X-ray flux variation and to correspond to the behaviour expected from neutron slowdown and eventual capture. In a review of the high-energy experimental flare results from SMM, P. Hoyng (Utrecht) argued that the preponderance of evidence now points towards the 'non-thermal' flare models (although, as pointed out by A. G. Emslie (Stanford), spatial characteristics of hard X-ray emission which may be attributed to a non-thermal model can also be predicted by some 'thermal' models).

The considerable flare emphasis of SMM may lead one to forget that one instrument aboard SMM was especially designed to observe phenomena on longer time scales — ACRIM, a cluster of three active cavity radiometers designed to monitor the possible variability of the solar bolometric luminosity. This important, but controversial subject was reviewed by S. Sofia (Goddard), and Hudson (UC San Diego), Woodard (UC San Diego) and Willson (JPL) reported luminosity fluctuations as large as ~ 0.2 per cent (probably associated with the passage of sunspot groups across the solar disk). ACRIM should help to answer some of the outstanding questions in this area, for example, it can now be shown observationally that the well known sunspot energy 'deficit' is not spatially redistributed in the vicinity of a spot on short time scales, suggesting that transient energy storage does indeed occur in the solar convection zone.

There is, of course, an enormous amount of solar physics conducted outside the SMM realm. J. Kohl (Harvard-Smithsonian CfA) and collaborators are using resonantly scattered Ly α photons as a diagnostic tool for coronal plasma above 1.5 solar radii. They have had two successful rocket flights, and G. Withbroe (Harvard-Smithsonian CfA) reported one of the first major results — that proton and

*The meeting of the Solar Physics Division of the American Astronomical Society was held 7–10 January 1981 at Taos, New Mexico.

R. Rosner is at the Harvard-Smithsonian Center for Astrophysics.

electron temperatures rapidly decouple above ~ 2 solar radii. The relative spatial constancy of the electron temperature, in contrast to the rapidly declining proton temperature with increasing radius, implies that the coronal heating process primarily couples to electrons, and is consistent with no significant proton heating (other than via e^- - p coupling) above ~ 2 solar radii. IMP satellite data (Borini, Stanford, and Gosling, Los Alamos) included the first definitive identification of (at least one of) the coronal sources of the low-speed solar wind, that is, the 'belt' of coronal streamers overlying photospheric neutral lines, and anomalously low He III abundances in the high plasma density wind regions associated with sector boundaries and (when mapped back to the Sun) coronal streamers. It is still debatable

whether yet other coronal source regions of the low-speed solar wind exist, these IMP results (particularly the He abundance anomaly), however, provide an important constraint for solar wind theorists.

Although experimenters did rather steal the show, theorists too were present at the meeting. Amongst the interesting theoretical results reported were the hydrodynamic calculations of the chromosphere, transition region and corona (McClymont and Canfield, UC San Diego, Boris and Mariska, NRL, and Pallavicini, Arcetri Observatory) which promise to resolve the controversy on the structure and stability of the 'confined' solar atmosphere, and convection zone calculations (Hurlburt and Toomre, JILA) which may help understanding of convection in the fully compressible limit. $\square$

neutron electric dipole moment, where such very small neutron spin rotations must be measured.

The present experiment, an Ispra/Harvard/Rutherford/Sussex collaboration, may be viewed as a neutron version of the standard crossed-polarizer configuration used in optics. Polarized neutrons pass from a polarizer through the tin samples, which are about 5 cm long, to a symmetric analyser, which yields neutron counts depending on the degree of spin rotation. Care must be taken to understand and eliminate magnetic field effects which could give spurious rotations by acting on the neutron magnetic moment, and various control and null tests were performed.

In classical fashion, the effect first showed up not in the material being studied (^{124}Sn) but in a control sample (natural tin) from which a large effect was finally located in ^{117}Sn .

Results for the three materials are ^{124}Sn , $(0.48 \pm 1.49) \times 10^{-6} \text{ rad cm}^{-1}$, ^{117}Sn , $(36.7 \pm 2.7) \times 10^{-6} \text{ rad cm}^{-1}$, $\text{Sn}(\text{natural})$, $(4.95 \pm 0.93) \times 10^{-6} \text{ rad cm}^{-1}$. Since natural tin contains only 7.6 per cent ^{117}Sn , there would appear to be a residual effect of $(2.16 \pm 0.95) \times 10^{-6} \text{ rad cm}^{-1}$ in natural tin not explained by its ^{117}Sn content. It should be noted that large parity-violating effects have shown up in ^{117}Sn before, in neutron radiative capture⁶.

In the context of the present picture of weak interactions, estimation of the size of the spin rotation effect would seem to be straightforward⁵. The neutron-atom weak interaction contains a term $\sigma \cdot p$, proportional to the helicity of the neutron, which creates a different index of refraction for each of the two helicity states of the neutron in matter. This in turn induces a rotation of the spin component perpendicular to the motion. The rotation in radians, Φ , for a neutron travelling a distance Z in a simple Born approximation calculation is

$$\Phi = \sqrt{2} G W p Z$$

where G is the Fermi weak interaction constant, ρ the number density of atoms and W a 'weak charge' for the atom. W is expected to be on the order of the number of particles in the atom, about 70 for example in the currently accepted electroweak theory of weak interactions. Among the

Neutron optical activity

from Leo Stodolsky

THE PHENOMENON of optical activity, in which a substance rotates the plane of polarization of light passing through it, is a familiar one. It is a common property of organic chemicals and is often used, for example, to measure their concentrations. Recently, a group working at the ILL (Institut Laue-Langevin) in Grenoble has reported¹ the first observation of the equivalent phenomenon for matter waves. Furthermore, the size of effect appears, in at least one case, to greatly exceed simple theoretical expectations. In an experiment using cold neutrons from the ILL research reactor (see the figure), Forte and his colleagues have seen the rotation of the spin of the neutron around its line of flight as it propagates in solid tin. A neutron with its spin direction perpendicular to its motion is a linear combination of two helicity (or circular polarization) states, just like a linearly polarized photon, therefore such a neutron beam is exactly analogous to plane-polarized light.

The neutron spin rotation observed differs from the optical activity of chemicals in one fundamental respect, however. In both effects a rotation (of the spin or plane of polarization) is coupled with a direction (line of flight) and demonstrates a 'handedness' or parity sense associated with the material. In the case of ordinary optical activity this handedness is traceable to the physical structure of the molecules of the material, which are in a configuration of definite handedness (stereoisomerism). A sample of tin, however, contains no such handed structures (The possibility of a neutron spin rotation created by handed materials,

through nuclear forces², or through magnetic interactions³, has been considered, but the predictions are quite small.) Thus the parity sense manifested by the neutron beam must be traced ultimately to a handedness in the interaction forces between the neutron and the constituents of the material — that is, to the phenomenon of parity violation in the fundamental interactions. Thus the small (10^{-6} rad) but definite rotation measured is a striking manifestation of a parity sense imparted to bulk matter by parity-violating forces.

The possibility of such a 'neutron activity' was, in fact, first suggested⁴ by Michel in 1964 as a way of seeing the parity-violating, weak interaction forces between the neutron and the atomic nucleus. The interest of the effect in connection with the question of 'neutral weak currents' and the possibility of observing the neutron-electron weak interaction was recognized seven years ago⁵ and brought to the attention of Norman Ramsey (Harvard University), who has been involved in a long series of experiments searching for a

Schematic view of experimental apparatus. The neutron beam polarization is along z and momentum along x .

Leo Stodolsky is at the Max-Planck Institute for Physics and Astrophysics, Munich

interesting features of the formula are that it is proportional simply to G and that, in contrast to ordinary optical activity, which must vanish at low frequency, it is energy independent. The observation of the effect with such low-energy (millivolt) neutrons appears to verify this last feature.

The size of the observed effect is surprising, however. The above theoretical formula for Φ , as well as more sophisticated calculations (for discussion and references, see ref. 7), lead to an estimate of about 10^{-8} rad cm^{-1} . This is 3,000 times smaller than that observed for ^{117}Sn .

The only explanation so far put forward to explain such a large discrepancy involves a very low-energy neutron (P-wave) resonance. In fact, the original motivation⁸ for studying ^{124}Sn — where, ironically, no effect at the 10^6 rad cm^{-1} level was found — was the suggestion of a resonant enhancement for the effect. In ^{117}Sn a weak resonance, which could be P wave, has been reported (1.2 eV). Even with the existence of such a resonance, however, it seems difficult to get an effect of the observed magnitude. This has prompted at least the present author to wonder whether there may not be some surprises lurking in the still not very well understood sector of the fundamental interactions concerning the non-leptonic weak interactions, particularly the weak interactions between nucleons⁸. The imperative question here is whether the large rotation is indeed some kind of special nuclear physics effect particular to ^{117}Sn and perhaps a few other rare nuclides, or whether there is something unexpected generally residing in the nucleon-nucleon force. In this respect the residual rotation for natural tin, beyond that expected from its ^{117}Sn content, is intriguing. If true, it indicates a large rotation on some other isotope also, and makes it much less likely that what is happening with ^{117}Sn is a freak occurrence. These questions can be clarified by measurements on a variety of nuclei, particularly the lighter ones, where the resonances are widely spaced and well known. Should the effect consistently turn out to be too large, it could point to the need to revise our understanding of the weak interactions on a basic level.

Finally, another interesting fact has emerged from this experiment. Motivated by the large rotation on ^{117}Sn , Forte and his co-workers looked for a dependence of the cross-section on the helicity of the neutron, that is, a difference in the rate of

neutrons transmitted through the material according to whether the spin is parallel or antiparallel to the direction of motion. This is also manifestly parity violating, and quantum mechanically is governed by (the imaginary part of) the same amplitude as the spin rotation. Here again a large effect is found. Although the authors say the result is too preliminary to be quoted as an actual cross-section, it is stated as being at about 9×10^{-6} of the total cross-section. The magnitude of this may be appreciated by saying that it corresponds to a cross-section at the tens or hundreds of μb level, a number more typical of say, electromagnetic than weak interactions, and hence appears 'big'.

This observation is something of an embarrassment to the theoretical workers in the subject. Although we had considered

the polarization dependence of the cross-section, the possibility that it could be finite, let alone 'big', at threshold was never considered since it would appear to involve inevitably a P-wave suppression factor. A finite parity-violating cross-section at zero energy is, in fact, possible, however, when an exothermic channel such as radiative capture or perhaps fission is present. This leads to an amusing and complex situation where, for example, the dominant process for the P-wave scattering is parity violating. Furthermore, because of the spin structure, some interesting tests of time reversal invariance should be possible in this novel system.

Although it is not at all clear that this situation is fully understood, it does seem clear that the door has been opened here to a new set of very interesting phenomena. □

Two DNA-binding proteins

from David Davies

THE last few years have seen dramatic developments in our view of DNA as a dynamic molecule, both in structure and function. Most of these properties can be attributed to the proteins that interact with DNA to produce replication, transcription, translation, transposition and processing. There are polymerases, synthetases, untwisting proteins, twisting proteins, histones, repressors, activators, but until recently very little was known about their three-dimensional structure or how, precisely, they interact with nucleic acid. This has now begun to change with the X-ray diffraction studies reported in this issue of *Nature* on two DNA-binding proteins, the cro repressor of bacteriophage λ (p 754) and the *E. coli* catabolite gene activating protein (CAP) (p 744). Although neither crystal structure actually involves the protein-DNA complex, the protein structures in both cases immediately suggest how the complex might form. The remarkable conclusion is made that while cro binds to right-handed B-DNA, CAP binds to left-handed B-DNA.

Cro is a small protein (molecular weight 7,351) that, together with the λ repressor protein, acts in the control of the lytic pathway of the bacteriophage³. The structure of the monomer at 2.8 Å resolution, as determined by Anderson *et al.*¹, is very simple, consisting of three extended segments forming an antiparallel β sheet, together with three helices. An

extended C-terminal tail interacts strongly with the corresponding tail of another monomer to form a dimer. This dimer associates in the crystal with another such dimer to form a tetramer, although in solution it is not known whether cro is a dimer or tetramer. However it is known that it binds to three sites on λ DNA, each of which exhibits some two-fold (palindromic) symmetry suggesting that the interacting form of the protein will be at least a dimer with two-fold symmetry.

Insight into the structure of the cro-DNA complex has come from a combination of genetics, chemistry and model building. Cro binds to a 17-nucleotide length of the DNA and prevents alkylation of the phosphates and methylation of the guanines at a site in the major groove. Cro appears to bind principally in the major groove of the DNA since methylation of adenine in the minor groove is not prevented by binding.

What parts of the cro structure could be involved in binding to DNA? One very suggestive feature is the helix from Gln 27 to Ala 36, which protrudes from the surface of the protein. The corresponding helix in the other subunit of the dimer is 34 Å away and each helix is inclined at 32° to the line joining their midpoints. These are the dimensions of the grooves on B-DNA and model building indicates that the helices can be positioned to fit convincingly into the major groove of right-handed B-DNA. Between the helices, some residues of the C-terminal segment form a pair of antiparallel β -sheet strands parallel to the minor groove which may interact

with it

Another regulatory protein, CAP, forms a complex with cyclic AMP and binds to specific DNA sites thereby altering the rate of transcription. The structure of the complex CAP-cAMP has been determined by McKay and Steitz at 2.9 Å resolution. The molecule is a dimer. Each subunit contains two domains joined by a 4–5 amino acid hinge region. There is a cleft between the two domains and in one subunit this cleft is open while in the other it appears closed, implying flexibility of the hinge analogous to that observed in immunoglobulins. The larger N-terminal domain interacts with the corresponding domain of another subunit to form a dimer in which there is local two-fold symmetry between the domains. There appears to be no interaction between the two smaller C-terminal domains.

As in the cro protein, the obvious candidates for binding to the DNA are two protruding helices, one from each of the C-terminal domains. However, unlike cro, these helices are oriented in such a way that they cannot fit into the grooves of right-handed B-DNA but could bind to the major groove of left-handed B-DNA. Such a model of the complex can account for the genetic and chemical data in a manner that could not be done with any model involving right-handed DNA.

Supporters of left-handed DNA recently received a boost with the discovery of the 'Z' structure for the alternating copolymer (dG-dC)⁴. However the [CAP-cAMP-DNA] complex proposed by McKay and Steitz involves left-handed B-DNA and not Z-DNA which has quite different helical dimensions. In 1979 Crick *et al.*⁵ examined the evidence on the handedness of DNA and concluded that there was little doubt that it was right-handed. Strong support for this conclusion has come from the recent dodecanucleotide crystal structure of Wing *et al.*⁶ who showed that the molecule is a right-handed B double helix. A modelling study by Gupta *et al.*⁷ has demonstrated that a left-handed model can be constructed for B-DNA, but experimental evidence

strongly favours the right-handed model.

McKay and Steitz therefore hypothesize that the handedness of the DNA at the binding site must change when it complexes with CAP. In view of the apparent flexibility of the protein hinge and the loose attachment of the DNA-binding domain to the major domain of CAP, this change of hand is a surprising accomplishment. McKay and Steitz have examined the possibility of rearranging the relative locations of the helices, for example by rotation about the hinge, but conclude that no simple rearrangement will provide a configuration complementary to right-handed B-DNA. Proof of this model will have to come from unwinding experiments on closed circular DNA, or from the crystallization of the CAP protein complexed to a small DNA fragment of appropriate sequence.

Given the complexity of protein structures, it is interesting that both the cro and CAP proteins have structures that immediately suggest that their principal means of interaction with the DNA is through α -helices sticking in the major grooves. The only crystallographic analysis of a nucleic acid-protein complex has been

that of protamine-tRNA⁸ which showed an α -helical piece of protamine lying in the minor groove of the tRNA. However, there have been other modelling proposals involving β -structure^{9–11} and the cro protein may also utilize the binding of an anti-parallel pair of strands in the minor groove of the DNA. Analysis of further DNA-binding proteins may reveal a more complex pattern of interactions although it should be remembered that DNA is a groovy molecule that might favour the binding of the ordered segments.

Although a model of DNA sequence recognition is not yet revealed by these studies, it is interesting that both proteins are at least dimers and can thus impose some 2-fold symmetry on the DNA binding site. Further information can be expected to come from a refinement and higher-resolution analysis of these and other structures. Also, although the three-dimensional structures of cro and CAP are quite acceptable, being based on experimental analysis with a proven technique, the predictions about the complexes are less secure and illustrate the need for crystal structure determinations directly of complexes of protein and DNA.

Laminin and epithelial cell attachment

from Brigid Hogan

THE past few years have seen an increasing interest in epithelial cells and the factors responsible for maintaining their organization into sheets and glands. The subject is important because most human tumours arise within epithelia, and metastasis involves cells breaking away from the territorial boundaries of these tissues and invading the surrounding stroma. Also important is the question of what distinguishes this pathological invasion by malignant carcinoma cells from normal migrations seen during the embryonic development of organs like the breast, when cords of cells burrow from the surface into the underlying mesenchyme to form complex branching ducts and tubes.

Such questions have focused attention on the physical boundary between epithelium and the stroma. In nearly all cases this is an extracellular basement membrane, or basal lamina, made up of proteoglycans, Type IV procollagen, fibronectin, laminin and other glycoproteins. Apart from restraining the wayward migration of epithelial cells by promoting their attachment and

alignment, roles suggested for the basal lamina include a means of laying down specific landmarks for cell guidance, acting as a filter for molecules of a particular size or charge, and the induction of epithelial cell differentiation. Given all this speculation, it is not surprising that the recent identification of the glycoprotein laminin¹ as a major constituent of basement membranes, both in the adult² and the embryo^{3–5}, has generated a whole spate of experiments on the effect of the purified protein on epithelial cells in culture.

Conveniently for the biochemist, laminin is made in large amounts by a number of mouse tumours, including the EHS 'sarcoma' (see ref 1) and several derived from an embryonic tissue known as parietal endoderm⁶. Laminin isolated from the matrix of these tumours consists of a very high molecular weight (approximately 900K), disulphide-bonded complex of three polypeptide chains, a larger one of about 450K and two smaller ones of very similar molecular weight (about 230K). Antibodies to laminin also immunoprecipitate a fourth polypeptide of molecular weight 150K, which is made in much larger amounts by normal rather than tumorigenic endoderm cells⁵, but the role of this laminin-related protein is not yet clear.

There is no doubt, however, that laminin is completely distinct from fibronectin, that other widespread component of basement membranes. In contrast to fibronectin, laminin is only made by epithelial cells and a few others including myotubes and neuroblastoma⁷ and not by fibroblasts. Although it is secreted into the medium of cultured cells, it does not by itself form an extensive fibrous network on both the upper and lower surfaces of monolayer cells, but accumulates as a matrix between the cells and the dish. Laminin does, however, seem to share some properties with fibronectin. Both bind to proteoglycans⁸ and to collagen, but whereas fibronectin binds to all collagens, laminin only seems to interact with Type IV procollagen, the species of collagen which is found in basement membranes. Very little is known about how these properties of laminin influence its deposition *in vivo*. In the skin, the basal lamina is composed of two layers, the *lamina lucida* next to the epidermis and the

lamina densa next to the dermis. Immunofluorescence studies have localized laminin to the *l lucida*² and Type IV procollagen to the *l densa*⁹ suggesting that here, at least, there is no intimate intermingling of the two components. Alternatively, laminin may be present throughout the basal lamina but its antigenic sites masked in the *l densa*.

Although its almost ubiquitous distribution in basement membranes suggests that laminin plays an important role in epithelial tissue organization, is there any real evidence for this? Studies in which epithelial cells were given a choice of collagen matrix on which to attach showed that they bind slowly but preferentially to Type IV procollagen¹⁰. It now appears¹¹ that this binding specifically requires laminin. Normally the cells make it for themselves slowly, but attachment can be speeded up by adding purified laminin, an effect which is blocked by anti-laminin antibody. Laminin also appears to be the active component of various conditioned media which promote epithelial attachment and growth¹². Fibronectin cannot substitute for laminin in these assays, and, conversely, laminin does not mediate the binding of fibroblasts to collagen. These results suggest, but by no means prove, that at least one *in vivo* role of laminin is to help epithelial cells keep their feet firmly on the ground.

It is an important feature of epithelial sheets and tubes that the cells are asymmetrical, with distinct basal and apical surfaces. During embryonic development

there are numerous descriptions of epithelial tissues emerging from clusters of precursor cells which are not themselves polarized in this way, and it is of interest that in two cases the onset of laminin synthesis seems to correlate with the time of this polarization. One example is the morula stage mouse embryo³ which at the time of compaction undergoes transition into a group of cells with definite inner and outer surfaces. The second example is the aggregation of mouse embryo kidney mesenchyme into tubules¹³. In both cases laminin synthesis may only be an early manifestation of epithelial differentiation, but it is also possible that its assembly into a basement membrane actually directs cell polarization in some way.

Finally, what happens to basement membrane laminin when epithelial cells metastasize? In a recent paper, Hayman and colleagues¹⁴ showed that after virus transformation, rat kidney cells lose the ability to lay down laminin and fibronectin in an extracellular matrix, even though they continue to synthesize the two glycoproteins at the same or increased rates. The authors speculate that a matrix cannot be organized by the transformed cells because of a change in their surface glycosaminoglycans, to which, as we have seen, both laminin and fibronectin bind. However, it could also be argued that the primary lesion is in the polarized cytoskeletal framework of the cells which allows them to spread their feet out over a surface, and through transmembrane connections keeps the matrix firmly anchored down. □

100 years ago

MR DARWIN ON VIVISECTION

"Dear Sir, — In answer to your courteous letter of April 7 I have no objection to express my opinion with respect to the right of experimenting on living animals. I have all my life been a strong advocate for humanity to animals, and have done what I could in my writings to enforce this duty. Several years ago, when the agitation against physiologists commenced in England, it was asserted that inhumanity was here practised and useless suffering caused to animals. It is right to add that the investigation of the matter by a Royal commission proved that the accusations made against our English physiologists were false. From all that I have heard however I fear that in some parts of Europe little regard is paid to the sufferings of animals, and if this be the case I should be glad to hear of legislation against inhumanity in any such country. On the other hand I know that physiology cannot

possibly progress except by means of experiments on living animals, and I feel the deepest conviction that he who retards the progress of physiology commits a crime against mankind. Any one who remembers, as I can, the state of this science half a century ago must admit that it has made immense progress, and it is now progressing at an ever-increasing rate.

"What improvements in medical practice may be directly attributed to physiological research is a question which can be properly discussed only by those physiologists and medical practitioners who have studied the history of their subjects, but, as far as I can learn, the benefits are already great. However this may be, no one, unless he is grossly ignorant of what science has done for mankind, can entertain any doubt of the incalculable benefits which will hereafter be derived from physiology, not only by man, but by the lower animals. Look, for instance, at Pasteur's results in modifying the germs of the most malignant diseases, from which, as it so happens, animals will in the first place receive more relief than man. Let it be remembered how many lives and what a fearful amount of suffering have been saved by the knowledge gained of parasitic worms through the experiments of Virchow and others on living animals. In the future every one will be astonished at the ingratitude shown, at least in England, to these benefactors of mankind. As for myself, permit me to assure you that I

honour, and shall always honour, every one who advances the noble science of physiology.

"Dear sir, yours faithfully,

"CHARLES DARWIN

Mr M G Mulhall sends us the following curious note, which we give without comment — "Although Shakespeare is supposed to have taken the idea of Hamlet from the Danish historian Saxo Grammaticus, there are such points of resemblance with the Arabic chronicle of Nigiaristan, respecting Montasser, tenth Caliph of Bagdad, that I venture to call your attention to the same. The points of analogy are as follows: 1 That Montasser is murdered by putting poison in his ear. 2 The ghost scene, in which his father appears to him. 3 The displaying of tapestry before the Caliph and his court, in which the tapestry represents a tragedy identical with the late Caliph's murder."

Mr H L Janssen van Raay writes to us from Batavia, March 21, that in the enumeration of the different geographical societies of the world in *Nature*, vol. xxiii p. 299, the Geographical Society at Samarang (Java), founded in 1879, was omitted.

From *Nature* 23, 21 & 28 April, 1880

ARTICLES

The Earth's radius and the G variation

V. M. Canuto

NASA Goddard Space Flight Center, Institute for Space Studies, New York, New York 10025 and
Department of Physics, The City College of the City University of New York, New York 10021, USA

It has long been assumed that if the gravitational constant G was larger in the past, the Earth's radius had to be smaller. The assertion holds provided the input from microphysics (in particular the equation of state) is independent of G . While this is true for some theories of gravity with variable G it is not so in the scale covariant theory, where the pressure can be affected by a variable G in a way that, for a constant mass of the Earth, a larger G in the past implies a larger Earth's radius. Comparison with recent palaeomagnetic data is presented.

MODERN observations¹ of increasing accuracy seem to confirm that the phenomenon of gravity is correctly understood in terms of Einstein's geometrical interpretation and satisfactorily described by the Einstein equations. There, therefore, seems to be no cogent reason to modify Einstein's theory as a description of gravity, as there is no reason to modify atomic theory. Within their limits, gravitational theory and atomic theory are complete and thus far satisfactory theories.

In cosmology, however, where gravitational phenomena involving large fractions of the age of the Universe are analysed not with gravitational but with atomic clocks, the two dynamics must be coupled. Let Δt_E (E for Einstein) be the time interval marked by a clock governed by gravitational dynamics (two orbiting planets, for example) and Δt the time marked by an atomic clock. Because the gravitational constant G and the total mass M may be thought of as the 'springs' of the gravitational clock, much in the same way as e , $\hbar$ and m may be considered the 'springs' of the atomic clock, then $\Delta t_E = f(G, M)$ and $\Delta t = g(e, \hbar, m)$.

To study the large times involved in cosmology a relationship between Δt_E and Δt as a function of time or equivalently of the age of the Universe is required. The lack of a unified theory of electromagnetic and gravitational forces, which would give us the answer, has been avoided so far by assuming that the ratio $\beta(t) = \Delta t_E / \Delta t$ at any time in the past was the same as today. This is known as the strong equivalence principle, SEP. While the adoption of the SEP has not yet led to flagrant disagreement with observations, it remains an unproved assumption, because its confirmation would require two measurements of $\beta(t)$ at two different times, the age of the Universe serving as a time scale. A more popular way of expressing a possible non-constancy of $\beta(t)$ is by saying that G may vary with respect to atomic time². In fact, a non-constant $\beta(t)$ is equivalent to one of the springs of the gravitational clock, say G , varying with respect to the atomic time.

Given the fundamental role of the SEP for the entire cosmological edifice, it is natural to expect that the nature of the function $\beta(t)$ be determined not by an *a priori* assumption, but by either a unified theory, which we do not have, or by observations of which we now have enough, covering a large fraction of the age of the Universe.

Cosmological data to put limits on β/β were used in ref 3 while the past luminosity of the Sun was analysed in refs 4 and 5. This article concentrates on the dependence of the radius of the Earth on $G = G(t)$.

The newtonian framework is shown to be unsuitable because it leads to inconsistencies (see refs 3, 4, 6, 7). Then it is shown that the Einstein framework leads, as expected, nowhere. Finally, the scale covariant theory is used through which the effects of a non-constant $\beta(t)$ can be treated and quantified consistently.

The Earth's radius

While the first analysis⁸ of the consequences of $G = G(t)$ dealt with the Sun's luminosity (the result $L_\odot \sim G^7$ has been shown⁴ to be $L_\odot \sim \text{constant}$, see also ref 5), more attention seems to have been given to the Earth's radius^{9,10}. The general consensus seems to be that if G was larger in the past, the Earth's radius had to be smaller (see, for example, refs 9–12).

To arrive at this qualitative conclusion, one uses (a) the hydrostatic equilibrium equation, (b) an equation of state and (c) the assumption of a constant total rest mass, ($\rho_0 = mn$, $n = N/V$, $M = mN$)

$$\frac{1}{\rho_0} \frac{dp}{dr} = -G \frac{m(r)}{r^2} \quad (1a)$$

$$p \propto \rho^\gamma \quad (1b)$$

$$M = \text{constant} \quad (1c)$$

thus deriving

$$R \propto M^{(\gamma-2)/(3\gamma-4)} G^{-1/(3\gamma-4)} \sim G^{-1/(3\gamma-4)} \quad (2)$$

which is the basic relation for all the qualitative conclusions that a larger G implies a smaller R , and therefore an expanding Earth.

While equations (1a), (1b) and (1c) form a set of consistent relations when G is constant, is the same true when G becomes a variable? The different exponentials of G and M in equation (2) are in sharp contrast with equation (1a) where G enters only in the combination GM . The asymmetry is introduced using an equation of state in the form (1b), which contains M but not G , the usual justification being that atomic relations are immune from whatever happens to G , which is valid only if gravity and atomic physics are kept separated. However, a variation of G represents a change of one dynamics with respect to the other, a process that can only be meaningful if we relate, not separate, the two dynamics. While the assumption that the two dynamics are disconnected may be logically consistent with the SEP, the purpose here is to relax the SEP allowing the two dynamics to depend on one another through the function $\beta(t)$ or equivalently $G(t)$. Furthermore, while we may reasonably expect an isolated hydrogen atom to be independent of β , this need no longer be true for a many-body quantity like an equation of state, which involves ingredients like the integration over phase space, the Liouville equation, as well as thermodynamic relations.

To show how equation (1b) may lead to incompatibilities with a $G = G(t)$, let us consider the equation of state $pV = NkT$, and use the adiabatic relation $TV^\Gamma = \text{constant}$, where $N = \text{constant}$, that is $M = \text{constant}$. We obtain $p \propto \rho^\gamma$ ($\gamma = 1 + \Gamma$), that is equation (1b) (equations (1b) and (1c) are, therefore, related). Furthermore, the basic ingredient in this derivation is the

adiabatic relation $TV^\Gamma = \text{constant}$, which comes from integrating the first law of thermodynamics, which in turn is a statement of conservation of energy

However, if $G = G(t)$, the potential energy $F = -G(t)m_2/r^2 = -\nabla V(r, t)$ becomes time dependent and we do not have energy conservation¹³. An inconsistency has surfaced.

The argument may be formalized by moving from the newtonian framework to the einsteinian one, not because general relativistic effects are relevant to the Earth, but because GR is the correct description of gravity. While the previous argument indicates that equations (1b) and (1c) are related, adopting the einsteinian framework will show that all the relations (1) are connected. In fact, the derivation of equation (1a) is based on the momentum conservation law, while equations (1b) and (1c) are related to the energy conservation law for the total energy density ρ . These laws can be combined into the conservation of the energy momentum tensor $T_{\mu\nu}$ (ref 14, equation 126.1), which in arbitrary coordinates reads

$$T^{\mu\nu}_{;\nu} = 0 \quad (3)$$

Let us now consider Einstein's equations,

$$G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R, \quad G_{\mu\nu} = -8\pi GT_{\mu\nu}, \quad (4a)$$

$$G^{\mu\nu}_{;\nu} = 0 \quad (4b)$$

Equation (4b) is the Bianchi identity, a geometrical relation valid irrespective of the content of the right-hand side of equation (4a)¹⁵. Clearly equations (1), or the global form, equation (3), are compatible with equation (4b) only if G is constant.

This argument indicates that taking G in equation (1a) variable is inconsistent with the simultaneous use of equations (1b) and (1c) in which G is absent not because it has no *a priori* right to be there, but because it has already been assumed to be constant.

The Einstein framework

Conventional general relativity is based on the existence of a metric field which obeys the Einstein field equations (4b) with or without the right-hand side (ref 16 and P. Bergmann, personal communication), $GT_{\mu\nu}$, a quantity that Einstein¹⁷ considered "a formal condensation of all those things whose comprehension in the sense of a field theory is still problematic". Equations (4a) were constructed from left to right¹⁵. Equation (4b) means that the right-hand side of equations (4a) must have zero divergence. While one may choose G to be constant, thus yielding $T^{\mu\nu}_{;\nu} = 0$ which embodies the 'standard' equations of motion and the 'standard' energy conservation equation, this choice is clearly not dictated by the theory of gravity. For that reason Einstein considered his theory 'incomplete', in the sense that it did not prescribe how to construct the source term from within. Given equation (4b), it would have been equally possible to choose

$$(GT^{\mu\nu})_{;\nu} = 0 \quad (5)$$

with G as a variable. Equation (5) indicates that $T^{\mu\nu}_{;\nu} = 0$, equation (3), is no longer true, because there is now a source term proportional to G . Because the energy conservation equation has acquired new terms involving G , so will the resulting equation of state. To summarize, as the energy-momentum tensor $T_{\mu\nu}$ is a function of the pressure p and the total energy density ρ , we have from equation (4) the two possibilities

G constant plus Bianchi identity $\rightarrow T^{\mu\nu}_{;\nu} = 0 \rightarrow p = p(\rho_0)$, $M = \text{constant}$

G variable plus Bianchi identity $\rightarrow (GT^{\mu\nu})_{;\nu} = 0 \rightarrow p = p(\rho_0, G)$, $M \neq \text{constant}$

independently of the specific form of $T_{\mu\nu}(p, \rho)$. To illustrate the modification to the p versus ρ relation, consider the following form for $T_{\mu\nu}$

$$T_{\mu\nu}(p, \rho) = (p + \rho)u_\mu u_\nu - pg_{\mu\nu} \quad (6)$$

By introducing the variables $p_* = pG$ and $\rho_* = \rho G$, we formally

reduce equation (5) to the standard form $T^{\mu\nu}_{;\nu} = 0$. Because G has 'disappeared', we recover again, as in the standard case $p_* \sim (\rho_0)_*$ and $M_* = \text{constant}$. Returning to the variables p and ρ_0 , we obtain finally

$$p \propto \rho_*^\gamma G^{\gamma-1} \quad (7a)$$

$$MG = \text{constant} \quad (7b)$$

Alternatively, as $T^{\mu\nu}_{;\nu} = 0$ implies $p_* dV + dU_* = 0$, on integrating, $(pV = NkT = \Gamma U)$, $NTGV^\Gamma = \text{constant}$. However, the zero pressure limit of $T^{\mu\nu}_{;\nu} = 0$ implies $nVG = NG = \text{constant}$, so that substituting T in $pV = NkT$, we recover equation (7a) (see also ref 4).

As for the hydrostatic equilibrium relation, the introduction of the new variables p_* and ρ_* has no effect on its structure, because G depends only on time. Equation (1a) is therefore consistent with a varying G .

Inserting equation (7a) into equation (1a), we derive,

$$R \sim M^{(\gamma-2)/(3\gamma-4)} G^{-1/(3\gamma-4)} G^{(\gamma-1)/(3\gamma-4)} \\ \sim (GM)^{(\gamma-2)/(3\gamma-4)} \sim \text{constant} \quad (8)$$

a result radically different from equation (2).

Alternatively, we can say that because only the starred quantities are physically meaningful, equations (1) should read ($\rho_0 = \rho$ for ease of notation)

$$\frac{1}{\rho_*} \frac{dp_*}{dr} = -\frac{m_*}{r^2}, \quad p_* \propto \rho_*^\gamma, \quad M_* = \text{constant} \quad (9)$$

which clearly show that G does not appear.

Scale covariant framework

The previous analysis has indicated that while it is in principle possible formally to make room for a variable G within the Einstein framework, the results turn out to be identical to those with a constant G . The message is that the quantity G has no 'identity' in such framework, thus confirming that there is no useful way of talking about a variable G within the Einstein theory.

To incorporate fully the possibility that atomic and gravitational times may differ over large fractions of the age of the Universe a formalism, the scale covariant theory (SCT) of gravity, was devised. A gauge function $\beta(t)$, epitomizing our ignorance of how gravity and atomic forces couple, was introduced through the equation

$$\Delta t_E = \beta(t) \Delta t \quad (10)$$

While the strong equivalence principle assumes $\beta(t) = \text{constant}$, a broad-based analysis of observational data ranging from astrophysics to cosmology (up to $z \approx 10^3$), gave no indication that $\beta(t)$ has to be constant^{3,4,6,7,18}. While this does not mean that $\beta(t)$ must be variable, it is a significant result once we consider that it was firmly believed that even simple data like the luminosity of the Sun would have clearly opposed the variability of $\beta(t)$. Furthermore, recent measurements of the period of the Moon by both atomic and gravitational clocks do not seem to yield the same result, the residual corresponding to

$$\frac{\dot{\beta}}{\beta} = (2.75 \pm 0.64) \cdot 10^{-11} \text{ yr}^{-1} \quad (11)$$

Gravitational times are defined as those times with respect to which the Einstein equations retain exactly their form as do all the purely gravitational expressions ensuing therefrom. However, with respect to atomic units, the gravitational equations take the form (ref 6, equation (2.10))

$$G_{\mu\nu} + f_{\mu\nu}(\beta) = -8\pi GT_{\mu\nu}(\beta) \quad (12)$$

The final aim of the SCT is to construct a viable two-times theory, within which the commonly assumed identity between atomic and gravitational times may be broken, $\Delta t \neq \Delta t_E$. For that to occur, the lagrangian $\mathcal{L}$ describing gravity and matter must not be scale invariant. While it is not *a priori* clear which of the

terms in $\mathcal{L}$ should break the symmetry, the choice is not large. Brands and Dicke (BD) chose the gravitational part $\mathcal{L}_g$, leaving $\mathcal{L}_m$, the matter part, unaltered. This implies that their $T_{\mu\nu}$ does not depend on β : the conservation law (3) holds unchanged, as do relations (1). Relation (2) is therefore consistent with the BD framework. However, the change in $\mathcal{L}_g$ means that the Einstein equations are modified by the addition of terms which coincide with our function $f_{\mu\nu}(\beta)$ only if the BD parameter ω is $-3/2$. The potentially most serious source of troubles facing a theory that alters the Einstein equations is that the expressions for the three fundamental tests acquire extra contributions which may spoil the ever increasing agreement with observations. As this seems to be the case in the BD theory, the SCT was constructed with the opposite point of view. The scale breaking terms were relegated entirely to $\mathcal{L}_m$, while the gravitational part of $\mathcal{L}$ was constructed in a scale invariant manner. The result is equation (12), where the function $f_{\mu\nu}(\beta)$ assures that the left-hand side of equation (12) is scale invariant, that is it has power zero under the scale transformation $ds \rightarrow ds' = \beta(x) ds$, where for any quantity A , we have $A \rightarrow A' = \beta^{\pi(A)} A$, $\pi(A)$ being the 'power' of A .

This approach has been questioned¹⁹ on the grounds that the 'presently accepted microscopic lagrangian' can be shown to be scale invariant (a more detailed discussion is given elsewhere). One of the critical quantities entering the analysis of ref. 19 is $\pi(m)$, the power of a microscopic mass m . From the fact that $\hbar/mc$ is a length, it follows that $\pi(l) = \pi(\hbar) - \pi(m) = +1$. The claim¹⁹ that $\pi(m) = -1$ can only be made if $\pi(\hbar) = 0$, which in turn implies $\pi(e) = 0$, because $e^2/\hbar c$ is a pure number. Now because the electric charge enters only in the lagrangian term representing interactions, any assumption about $\pi(e)$ is an assumption about the scaling property of the interaction. Because of the general relation $\beta GM = \text{constant}$ (see equation (14)), $\pi(m) = -1$ implies $g = 2$. Now considering the electromagnetic tensor $F^{\mu\nu}$, if the contribution to $T_{\mu\nu}$ from the free electromagnetic field is taken to be scale invariant then the power of $F^{\mu\nu}$ is $-3 - g/2$ which is -4 . Because $J^\mu = enu^\mu$ has power -4 , the interaction equation $F^{\mu\nu}{}_{;\nu} = J^\mu$ is scale invariant. As such, it may not hold in the SCT because the final aim is that of allowing atomic clocks to scale differently from gravitational clocks. Because the gravitational part $\mathcal{L}_g$ has been constructed in a scale invariant form (hence scale invariant theory of gravitation) with the result that the period of a planet with respect to atomic clocks scales like $P \sim \beta^{-1}$ (ref. 6, equation (4.19)), clearly the dynamic equation governing an atom cannot be $F^{\mu\nu}{}_{;\nu} = J^\mu$ because being scale invariant, it would yield $P(\text{atom}) \sim \beta^{-1}$ too, thus leading to no difference between atomic and planetary dynamics, that is to a constant G . If we accept 'the presently accepted form of $\mathcal{L}_m$ '¹⁹ (an equation like $F^{\mu\nu}{}_{;\nu} = J^\mu$) then clearly the only possibility for a varying G is to go back to $\mathcal{L}_g$ and to devise a modified BD approach. This line of reasoning, which does not contemplate the possibility advocated by the proponents of the SCT, cannot be taken to imply nor to have proved that either (1) G is constant or (2) that for it to vary, the only avenue open is $\mathcal{L}_g$. Progress in modifying $F^{\mu\nu}{}_{;\nu} = J^\mu$ using gauge fields and neutral current concepts, has recently been made (P. J. Adams and J. Anderson, personal communication). Far from being mutually exclusive, the approach proposed in ref. 19 and the point of view of the SCT are in our opinion but different approaches towards the same goal.

Let us now prove that βGM is constant. It has been shown⁶ that the left-hand side of equation (12) has zero co-covariant derivative (indicated by * instead of ,). We therefore have, using equation (A.19) of ref. 6 and the fact that $G_* = 0$,

$$T^{\mu\nu}{}_{;\nu} + (\pi + 6)\phi_{,\nu} T^{\mu\nu} - \phi^{\mu} T^{\nu}{}_{;\nu} = 0 \quad (13)$$

with $\phi \equiv \ln \beta$, $\phi_{,\nu} \equiv \phi_{,\nu}$. The quantity π is the power of $T^{\mu\nu}$. Multiplying equation (13) by u_μ and using for $T_{\mu\nu} = \rho_0 u_\mu u_\nu$, we obtain on integrating ($\rho_0 V = M$)

$$\beta GM = \text{constant} \quad (14)$$

where $V/V = u^\mu{}_{;\mu}$, and $\pi = \pi_{S1} = -4 - g$, $g = \pi(G)$. We have

required that the right-hand side of equation (12) be scale invariant, $\pi(GT_{\mu\nu}) = 0$. Equation (14) makes it clear that the power of m must be chosen consistently with the dynamical constraints of the theory, and not assumed *a priori*. In fact because $\pi(m) = 1 - g$, a $G\beta^2 = 1$ gauge yields $\pi(m) = -1$, whereas $G\beta = 1$, the so-called non-matter creation case, yields $\pi(m) = 0$.

The very fact that in equation (12) $T_{\mu\nu}$ is taken to depend on β implies, even without further qualifications, that we cannot use, without checking their validity, any of the standard relations (1a), (1b) and (1c) because, strictly speaking, they are valid only for constant β . The β dependence of microscopic relations, marking a sharp contrast with the BD theory, is the price one must pay for constructing a theory with a built in two-times scheme and which at the same time preserves the agreement between observations and predictions for the fundamental tests, whose expressions in atomic units can be derived by direct scaling of the corresponding gravitational expressions. Because at any given time the scale function $\beta(t)$ can be normalized to unity, a set of measurements at one time cannot reveal the presence of β . In this sense, the SCT theory has preserved agreement with the three tests⁷. The scaling of gravitational expressions to obtain the corresponding atomic ones is all that is required when dealing with purely gravitational phenomena, like periods or distances of planets, which by assumption are given by Einstein equations and are constant with respect to gravitational clocks. On the other hand, non-gravitational quantities must be derived consistently with equation (13), so that the influence of the function β can be fully accounted for. This is a major endeavour because it calls for a reconstruction of microscopic physics, a process which, while accounting for the fact that β can enter at any stage, must satisfy the following two constraints: (1) the atomic clock ensuing from such theory must not depend on β , (2) the many-body behaviour of the theory must yield results consistent with the classical ones derived from equation (13). A typical example of such 'matching' relation is the continuity equation, $\rho + \rho \text{div } J = 0$, which can be obtained both from equation (3) and from the Schrodinger equation. These requirements clearly indicate that the attempt at constructing such theory is far more complex and difficult than that faced by Brans and Dicke. Descending from the Einstein equation to microphysics (thus running in the opposite direction to the traditional one, which assumes the validity of the microscopic scheme and makes connection with gravity by going from a flat to curved space) has to my knowledge never been worked out in detail. In spite of this, we have already derived⁶ the influence of β on several microscopic relations, and the corresponding observational implications such as the energy versus frequency for a free photon, the adiabatic scaling law for a perfect gas, the equilibrium radiation versus frequency and temperature expression, and the luminosity versus distance relation (see also ref. 5). No contradictions have yet appeared.

Having clarified this point, let us return to the original problem of evaluating R as $R(t)$. The full problem is very complex because we do not yet possess a full description of atomic interactions which determine the equation of state for an object like the Earth. We can therefore present only a hopefully good approximation to the exact solution. Returning to equation (13), and using for $T_{\mu\nu}$ equation (6), we first separate out the rest mass contribution from the total energy density ρ , $\rho = \rho_0 + u$. The rest mass part of equation (13) can be easily integrated. The result is equation (14). The $\rho - \rho_0 = u$ part satisfies the equation ($U = uV$)

$$dU + p dV + [(1 - g)U + 3pV] d\phi = 0 \quad (15)$$

which is the first law of thermodynamics generalized to include the β terms³. Let us now write

$$p = \frac{N}{V} kT \left[1 + B(T) \frac{N}{V} + C(T) \left(\frac{N}{V} \right)^2 + \dots \right] \quad (16)$$

where $B(T)$ and $C(T)$ are the so-called virial coefficients²⁰. We first consider the perfect gas case, $B = C = 0$. Using $pV = NkT$

and $U = NkT/\Gamma$ and remembering that $N \sim (\beta G)^{-1}$, we integrate equation (15), with the results ($\gamma = 1 + \Gamma$)

$$p \propto \rho_0^\gamma \left(\frac{G}{\beta^2} \right)^{\gamma-1} \quad (17a)$$

$$T\beta^{3\Gamma} \sim \frac{1}{V^\Gamma} \quad (17b)$$

For a more general derivation, valid for non-adiabatic transformations, see ref 5

Note that there is no choice of gauge, a G versus β relation, that reduces equations (17a) and (14) to equations (1b) and (1c), at least for $\gamma \neq 1$. In fact, to recover equation (1b), we must choose $G \sim \beta^2$, which implies $\beta < 0$, contrary to equation (11). This choice would also imply $M \sim \beta^{-3}$, not $M \sim \text{constant}$. To see the consequences of equation (17a), we use it in equation (1a), which has already been shown⁶ to be valid in the present framework

$$R \sim M^{(\gamma-2)/(3\gamma-4)} G^{-1/(3\gamma-4)} \left(\frac{G}{\beta^2} \right)^{(\gamma-1)/(3\gamma-4)} \sim \frac{1}{\beta} \quad (18)$$

on using equation (14). The result is independent of γ . We therefore conclude that

$$\frac{R}{R_0} = -\frac{\beta}{\beta_0} = -(2.75 \pm 0.64) 10^{-11} \text{ yr}^{-1} \quad (19)$$

where we have used equation (11). The predicted value of R , 400 Myr ago, is therefore ($R_0 = 1$)

$$R = 1.0110 \pm 0.002 \quad (20)$$

which can be compared with the recent palaeomagnetic result¹²

$$R = 1.020 \pm 0.028 \quad (21)$$

At first sight, the close agreement can be taken as justification for the approximations made to arrive at equation (18). However, a closer scrutiny reveals that the result must be taken with great care. First, as stressed in ref 12, an equation of state of the form of equation (17a), is not valid at the surface of the planet where $p = 0$ but $\rho_s \neq 0$. The criticism is clearly independent of G and β . More important, however, is that the result $R \sim \beta^{-1}$ implies that the radius of the Earth in einstein units $R_E = \beta R$ is constant. While possible, this result is not obvious because atomic quantities like e and m , which enter the relation p_E as $p_E(\rho_E)$ and therefore R_E , are not constant in einstein units.

Having discussed the limitations of equation (17a), we go back to equation (16) and include the interaction term $B(T)$ in the form $B(T) = -BT^{b-1}$. We simulate in this phenomenological way an attractive potential. Although equation (17b) is valid when $B = 0$, it is used because we are performing an approximation to the first term. Equation (16) then becomes ($\rho_0 = \rho$ for ease of notation)

$$p = A\rho^\gamma \left(\frac{G}{\beta^2} \right)^{\gamma-1} \left[1 - \frac{B}{A} \rho^{\tilde{\gamma}} \left(\frac{G}{\beta^2} \right)^{\tilde{\gamma}-1} \right] \quad (22)$$

where $\gamma = 1 + \Gamma$, $\tilde{\gamma} = \gamma_* - \gamma$, $\gamma_* = 2 + (\gamma - 1)b$. An equation of state for the Earth of the type (22) (for $G = 1$ and $\beta = 1$) has been proposed by Birch²¹ with $\gamma = 7/3$ and $\gamma_* = 5/3$. While equation (17a) allows an exact solution, equation (18), equation (22) does not. For our purposes

$$R \sim \frac{1}{\beta} \left[1 - \frac{B}{A} \bar{\rho}^{\tilde{\gamma}} \left(\frac{G}{\beta^2} \right)^{\tilde{\gamma}-1} \right]^{1/(3\gamma-4)} \quad (23)$$

where $\bar{\rho}$ is an average (but time dependent) density. We further derive

$$\frac{R}{R_0} = -r \frac{\beta}{\beta_0}, \quad r - 1 = \frac{(2+g)\alpha}{\mathcal{D} - 3\tilde{\gamma}\alpha} \quad (24)$$

where $\mathcal{D} = 3\gamma - 4$, $\alpha = x(1-x)^{-1}$, $x = (B/A)\bar{\rho}^{\tilde{\gamma}} (G/\beta^2)^{\tilde{\gamma}-1}$. For the values of γ and γ_* given by Birch, we have $r - 1 = (2+g)\alpha/(3+2\alpha)$, which for $g = 1$ ranges from zero ($\alpha = 0$) to $3/2$ ($\alpha =$

∞). The first value corresponds to equation (18), $\alpha = \infty$ implies $x = 1$, that is $\bar{\rho} = \rho_s$, not acceptable. If p must vanish at $\rho = \rho_s$, then $x = (\bar{\rho}/\rho_s)^{\tilde{\gamma}}$. In spite of the large excursion in α , the corresponding variation in $r - 1$ is only from 1 to 1.5. Taking $\alpha = 1$ ($x = 1/2$, corresponding to $\bar{\rho} = 8 \text{ g cm}^{-3}$, $\rho_s = 2.84 \text{ g cm}^{-3}$) and $g = 1$, we have $r = 1.6$, so that 400 Myr ago

$$R = 1.018 \pm 0.004 \quad (25)$$

in better agreement with equation (21). Finally equation (24) may alternatively be written, using equation (14),

$$R \sim (GM)^r, \quad \frac{R}{R_0} = r \frac{(GM)}{GM} \quad (26)$$

to be compared with equation (2). As r is positive (at least for $g + 2 > 0$) the SCT predicts a result qualitatively different from equation (2) for a constant mass M , a larger G implies a larger radius, not a smaller one.

The method used to arrive at equation (22) is not meant to be a microscopic derivation of the p versus (ρ, β) relation for the Earth, but only an heuristic approach to show how β may enter the problem. Even without β , it is difficult to derive²² an equation of state for the Earth. Because all the $p = p(\rho)$ relations discussed in ref 22 contain no β and because $\beta = 1$ corresponds to einstein units, one might be tempted to think that the relations in ref 22 are actually valid in gravitational units and that a simple scaling could then yield the corresponding atomic relations. This is, however, not the case. Such a procedure would yield a relation where the difference of the power of ρ and that of (G/β^2) is unity, like the first term of equation (22). In turn this yields $r = 1$. It can be seen that $r - 1$ is directly proportional to the difference of these two exponents. Furthermore, $r = 1$ implies $R_E = \text{constant}$ producing difficulties already discussed. With the present procedure, this does not happen. The powers of ρ and that of (G/β^2) of the second term of equation (22) do not differ by one but by two. An extra term $(G/\beta^2)^{-1}$ appears which makes $r \neq 1$. This extra factor, which breaks the symmetry that one would invariably get out of a simple scaling process, cannot be arrived at from gravitational units where $\beta = \text{constant}$.

Lunar data

Having derived equation (24) but having no estimates for β/β_0 from within the theory, we can either use palaeomagnetic data for R/R_0 and thus determine β/β_0 (and possibly G/G_0), or we evaluate β/β_0 from other data and then compare the resulting R/R_0 with palaeomagnetic data. The only other data available are the rate of change of the Moon's period measured in both atomic and gravitational units: these are ($P = 2\pi/n$ is the period of revolution of the Moon)

n_E (gravitational time) (arc s cyr ⁻²)		n (atomic time) (arc s cyr ⁻²)	
-26.0 ± 2.0	ref 23	-21.4 ± 2.6	ref 26
-28.5 ± 3.1	ref 23	-23.6 ± 1.5	refs 26, 27
-30.0 ± 3.0	ref 7	-24.6 ± 3.9	refs 26, 28
-27.4 ± 3.0	ref 24		
-30.6 ± 3.1	ref 25		

where, because of equation (10), $n = \beta n_E$. A least-square fit analysis yields (β/β_0 in 10^{-11} yr^{-1}), note that $1 \text{ cyr} = 10^3 \text{ yr}$

$$\text{All equations} \quad n_E = -27.97 \pm 0.78, \quad \beta/\beta_0 = 2.75 \pm 0.64 \quad (28a)$$

$$\text{First } n_E \text{ deleted} \quad n_E = -29.11 \pm 0.73, \quad \beta/\beta_0 = 3.41 \pm 0.54 \quad (28b)$$

$$\text{Second } n_E \text{ deleted} \quad n_E = -27.87 \pm 0.91, \quad \beta/\beta_0 = 2.69 \pm 0.72 \quad (28c)$$

Because the value of β/β_0 retaining all the eight equations turns out to fall between the other two, we have adopted this value, equation (11). Finally, independently of the way we determine β/β_0 (palaeomagnetic or lunar data), the value of G/G_0 is gauge dependent and is to be determined using the relations $G/G_0 = -g\beta/\beta_0$, $\pi(m) = 1 - g$

Moment of inertia

Using equation (24), and $M = \text{constant}$ we obtain $I/I = -2r\beta/\beta$, or equivalently $I/I = 2rG/G$, with $r > 0$. This result agrees with equation (A 16) of ref 29, because the G in equation (A 1) must be written as $G_* = G(\beta^2/G)^{\gamma-1} = G^{4-3\gamma}$, due to equation (17a). If so, equation (A 16) becomes $I/I = aG/G$, with $a = (3\gamma - 4)/10 > 0$.

This result is, however, of limited use because it is in atomic units and it represents only the cosmological and not the total contribution to I/I , whereas the estimates reported in the literature are total variations—due to all possible causes, cosmological and otherwise—and they are all with respect to gravitational units. To prove this last point, we must remember that the basic ingredient (see refs 30, 31) is the conservation of the total angular momentum for the Earth–Moon system $J_E + L_E = \text{constant}$. If the Earth is considered a point mass, this implies the conservation of the orbital angular momentum L_E , a law valid only with respect to gravitational units^{6,7}. In atomic units L scales like $L \sim \beta^2/G$ ($\sim G^{-3}$ for constant mass) (ref 6, equation 4.7).

We now consider I_E/I_E from all sources and expressed in gravitational units. While growth lines in fossils promised to be a valuable source of information³⁰, recent difficulties in interpretation have indicated that quantitative results are not yet possible³². We shall therefore rely on ancient astronomical data (see Chapter 10, ref 31), and take equation (10.2.2b) from ref 31 and generalize it to include a non-constant I_E . We obtain

$$\frac{I_E}{I_E} = -\frac{\Omega_E}{\Omega_E} + \frac{\gamma}{3} \frac{n_E}{n_E} + H \quad (29)$$

where $\gamma = (1+b)L_0/J_0$, b accounting for the solar contribution. H represents the contribution of the time variation of dynamical elements describing the size, shape and orientation of the Earth–Moon system. If $J = I\Omega \cos \phi$, and $L = M_e M_m / (M_e + M_m) \times R^2 n (1-e^2)^{1/2} \cos i$, then $H = H(e, \phi, di/dt)$ (see ref 33).

Ancient astronomical observations can be used³¹ to construct a relation of the form $X_i n_E + Y_i \Omega_E = f$, where X_i and Y_i are numerical coefficients and f is a function of the observed less the computed position of the recorded event. As stated by Lambeck³¹ “the computed positions and locations” are arrived at “assuming purely gravitational motion”, further substantiating our claim that the ingredients are the standard newtonian equations which hold only with respect to dynamical units with G_E and M_E constant. Lambeck summarizes the results as follows

$$n_E = -28 \pm 2, \quad \Omega_E = -1,100 \pm 100 \quad (30)$$

This value for n_E is not substantially different from the one determined in equation (28). Using $L_0/J_0 = 4.89$ and $b = 0.21$, we obtain from equation (29)

$$\frac{I_E}{I_E} = -(0.086 \pm 0.031) 10^{-9} \text{ yr}^{-1} + H \quad (31)$$

To complete the computation we must now evaluate and then subtract from equation (31) the purely cosmological contribution. This is done by remembering that $I_E \sim M_E R_E^2 \sim \beta^2 R^2$, and using equation (24)

$$\left(\frac{I_E}{I_E}\right)_{\text{cosm}} = 2 \frac{(\beta R)}{\beta R} = -2(r-1) \frac{\beta}{\beta} = -(0.033 \pm 0.008) 10^{-9} \text{ yr}^{-1} \quad (32)$$

The difference

$$\frac{I_E}{I_E} - \left(\frac{I_E}{I_E}\right)_{\text{cosm}} = -(0.053 \pm 0.032) 10^{-9} \text{ yr}^{-1} + H \quad (33)$$

may now be attributed to geophysical phenomena such as the formation of the Earth's core³⁰. For the evaluation of H see ref 33.

Conclusions

The question whether a viable theory of gravitation exists that permits equations (1a), (1b) and (1c) as they are, while G is taken to vary, has been investigated with the following results.

Standard Einstein theory can be formally generalized to include a non-constant G . While equation (1a) remains valid, both equations (1b) and (1c) change in such a way that the final result is $R = \text{constant}$, demonstrating that G is actually a non-entity within the strict framework of Einstein.

In the BD theory, as by construction the matter lagrangian is not changed, equations (1) and (2) both hold. However, it is believed that the BD theory faces difficulties, at least in its present form.

Finally, while equation (1a) holds unchanged in the SCT equations (1b) and (1c) cannot be simultaneously satisfied. The most interesting result, however, which transcends the particular example equation (22), is that microphysics may be affected by a variable G . This may seem unusual at first as microphysics contains no G thus creating the impression that it ought to be immune from whatever happens to G . However, relations like the Boltzman equation, the radiative transfer equation, and the Navier–Stokes equations are derivable from and are consistent with the conservation law $T^{\mu\nu}_{;\mu} = 0$ for the energy momentum tensor, a law which holds only if G is constant, as equation (13) shows. The absence of G is actually a consequence of having chosen it to be constant.

More general derivations of classical non-gravitational relations (such as, Liouville equation⁵, Boltzman distribution⁵, radiative transfer equation⁵ and classical thermodynamics^{3,6}) in which β does explicitly appear, are possible, if constructed consistently with the general conservation laws that follow from the Einstein equation. For example, an equation of state of the form (17a) with $\gamma = 4/3$ holds^{3,6} for radiation (ρ_0 is replaced by the photon number density n_γ). Because $3p_\gamma = \rho_\gamma$ and $n_\gamma T \sim \rho_\gamma$, $\rho_\gamma \sim (\beta^2 G^{-1}) T^4$. It then follows that the Sun's luminosity $L_\odot$ scales like $L_\odot \sim \beta^{-1}/k$, where k is the opacity. For constant k and constant rest mass, $L_\odot \sim G$, contrary to the early statements that $L_\odot \sim G^7$ (for details, see refs 4, 5).

Our comparisons of the theoretical predictions with observations must be treated cautiously. The value of β/β derived from lunar data and used to estimate equations (20) and (25) is still subject to uncertainties due to the difficulties in estimating the errors, there are also doubts concerning palaeomagnetic data, or more precisely the assumptions made to arrive at equation (21) (ref 10, see, however, ref 34). Finally the evaluation of the function H , equation (33), is still fraught with large errors (see ref 33).

We prefer, therefore, to focus the dependence of R on G . If we write, in atomic units,

$$\frac{R}{R} = \left(\frac{R}{R}\right)_{\text{cosm}} + \left(\frac{R}{R}\right)_{\text{othersources}} \quad (34)$$

the present work predicts a reversal (compared with the standard treatment, equation (2)), of the sign of the first term in equation (34) when written in terms of G/G , equation (26).

This is in turn due to the new effect represented by the presence of G in the $p = p(\rho)$ relation. The G in the right-hand side of equation (1a) is overcompensated by the $G^{\gamma-1}$ factor in equation (17a), thus causing a larger G to correspond to a larger radius. However, the evaluation of the second term in equation (34) is outside the scope of this article, and we cannot conclude from our work alone that R is actually decreasing.

I thank Drs G. Blake, D. J. Stevenson and J. Anderson for constructive criticism, also Drs T. C. Van Flandern, S.-H. Hsieh, P. J. Adams, I. Goldman, J. R. Owen, K. M. Creer and J. D. Mulholland for assistance during the preparation of this manuscript.

Structure of catabolite gene activator protein at 2.9 Å resolution suggests binding to left-handed B-DNA

David B. McKay & Thomas A. Steitz

Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, Connecticut 06511, USA

The 2.9 Å resolution crystal structure of Escherichia coli catabolite gene activator protein (CAP) complexed with cyclic AMP reveals two distinct structural domains separated by a cleft. The smaller carboxy-terminal domain is presumed to bind DNA while the amino-terminal domain is seen to bind cyclic AMP. Model building studies suggest that CAP binds to left-handed B-type DNA, contacting its major groove via two α-helices. It is possible that the CAP conversion of right- to left-handed DNA in a closed supercoil, is what activates transcription by RNA polymerase.

REPRESSOR and activator proteins that regulate gene expression at the level of transcription recognize specific nucleotide sequences in double-stranded DNA. Although it has been suggested that specific recognition involves α-helices fitting into the major groove of B-DNA¹⁻³ or anti-parallel β-strands in the minor groove⁴, no experimental evidence exists concerning the actual mode of sequence-specific interaction between protein and double-stranded DNA. Also, the molecular mechanism by which gene activators promote the activity of RNA polymerase, thereby switching on genes, remains unknown. We present here the structure determination of a protein that binds in a sequence-specific manner to double-stranded DNA and propose a mechanism by which the catabolite gene activator protein is able to switch on the catabolite-sensitive genes.

The catabolite gene activator protein (CAP), also called the cyclic AMP receptor protein, functions in *Escherichia coli* in the regulation of several catabolite-sensitive gene operons^{5,6}. Regulation by CAP is exerted at the transcriptional level with cyclic AMP acting as an allosteric effector. In the presence of a sufficient concentration of intracellular cyclic AMP, cyclic AMP forms a complex with CAP which binds to specific DNA sites near the promoters of several operons and alters the rate of their transcription by RNA polymerase. In the lactose (*lac*)⁷ and arabinose⁸ operons, the cyclic AMP-CAP complex is a positive regulator—it potentiates transcription. In the galactose operon, the presence of two overlapping promoters for RNA polymerase makes the situation more complex, cyclic AMP-CAP is required for initiation of transcription from one promoter, but inhibits transcription from the other. Thus, in this case it apparently acts as both a positive and negative regulator of operon expression⁹.

The active form of CAP is a dimer of identical subunits of molecular weight 22,500 and 201 amino acid residues^{10,11}. Proteolytic cleavage studies are consistent with the CAP subunit

having two separate structural domains¹². Results from a variety of techniques¹²⁻¹⁷ suggest that CAP undergoes a significant conformational change on binding cyclic AMP.

To develop a structural basis for understanding (1) the cyclic AMP-induced allosteric transition in CAP, (2) the site-specific recognition of DNA by CAP, and (3) the mechanism of transcription activation by CAP, we have initiated crystallographic studies of CAP and its complexes with ligands. In this article we report the structure of the cyclic AMP-CAP complex at 2.9 Å resolution.

Structure determination

CAP protein was purified and crystallized in the presence of 0.5 mM cyclic AMP as previously described¹⁸. The crystals are orthorhombic, space group P2₁2₁2₁, *a* = 46.5 Å, *b* = 97.1 Å, *c* = 105.4 Å, with one dimeric CAP molecule per asymmetric unit.

Intensities of crystallographic reflections were measured by diffractometer, using the Wyckoff scan algorithm¹⁹. Friedel pairs of reflections were measured on native crystals and five heavy-atom derivatives, for derivative data sets only ~75% of the total reflections, consisting of those which were most intense in the native data, were measured. Heavy-atom positions were located and refined by conventional methods²⁰ and the correct enantiomorph of the heavy-atom positions was determined using anomalous difference Fourier²¹. A summary of heavy-atom derivative preparation and refinement statistics is presented in Table 1. Combined multiple isomorphous replacement and anomalous scattering phases were computed to 2.9 Å resolution and had an average figure of merit of 0.74.

Part of the electron density map is displayed in Fig. 1. Most of the polypeptide backbone is well ordered and can be traced unambiguously in both subunits, however, regions of local disorder are encountered at the amino termini, the carboxy

where I = diffraction intensity, f_H = calculated heavy-atom structure factor amplitude, F_P = structure factor amplitude of native crystals, and F_{PH} = structure factor amplitude of derivative crystals. Summations are overall reflections, n

termini and a coiled structure in the smaller domain marked A and A'.

Approximate α -carbon positions were obtained by placing markers on map sections and measuring their coordinates. Polarity of the polypeptide chain was established from the tilt of the larger side chains on the α -helices. Although many side chains are clearly visible in this map, no attempt has yet been made to place the several fragments of amino acid sequence obtained by Schlesinger. Cyclic AMP was identified because it was not continuously connected with the polypeptide backbone, included the most dense feature in the map (presumably the phosphate) and was too large to be an amino acid side chain.

Subunit morphology

The CAP subunit is folded into two distinct structural domains (Fig. 2). The larger amino-terminal domain has approximate overall dimensions of $25 \times 30 \times 35$ Å. It contains ~135 amino acid residues and consists primarily of a pair of helices (A and B, Fig. 2) which lead into an antiparallel β -strand folded into an eight-strand β -roll, also, a 40 Å-long α -helix C connects the two domains and partially closes off one end of the interior pocket formed by the β -roll. This helix extends from the small domain to the distal extremity of the large domain rather than forming a short, proximal bridge between the two domains. The topology of the eight-strand β -roll, sometimes referred to as the 'Swiss roll', has recently been observed, with minor variations, in three protein structures: the 'shell' domain of tomato bushy stunt virus protein²², Southern bean mosaic virus protein²³ and influenza haemagglutinin⁴⁶.

The carboxy-terminal domain is smaller, with approximate dimensions $20 \times 20 \times 30$ Å. It has about 65 amino acid residues and contains three distinct α -helices, D, E and F, the D helix is ~24 Å long, the F helix ~22 Å long, whereas the E helix is

rather short. Much of the small domain consists of irregular structure, some of which is partially disordered. Although the electron density marked AA' in Fig. 1 and corresponding to the region circled in Fig. 2 is well above the background level of the solvent region, it is not sufficiently well defined to place α -carbon positions with complete assurance. Thus, the polypeptide path shown in Fig. 2 at the carboxy terminus of the D and F helices illustrates only the general folding of the subunit in these regions and the connections within the circled region may have to be altered when amino acid sequence data are fitted to the electron density map. As the number of amino acid residues in our model is very nearly that expected from amino analysis^{10,11}, no significant portion of the molecule can be missing from the model.

Although there is a distinct cleft between the two domains of the CAP subunit, noncovalent contacts occur between them that presumably stabilize the relative orientation of the domains. Both subunits contain one similar region of noncovalent contact between their large and small domains: the end loop connecting strands 4 and 5 of the β -roll in the large domain is in contact with a loop of coil in the small domain. In addition, in one of the subunits, there is a second point at which the carboxyl end of the D helix may be within noncovalent contact distance of strand 5 of the β -roll of the large domain.

Dimer morphology

As the structures of the two subunits of the CAP dimer differ, there is no unique dyad axis relating them (Figs 3–5). Qualitatively, the cleft of one subunit appears 'closed' to the point of extensive van der Waals' contact between the large and small domains while the cleft of the second subunit is 'open', that is, the two domains have different relative orientations in the two subunits. Quantitatively, if the two large domains are super-

Fig. 1 Part of the electron density map, 81 Å horizontal by 71 Å vertical by 10 Å depth. Only positive contours are shown, the contour interval is approximately one-sixth the maximum peak height. The dashed line circumscribes one CAP molecule. The two oblong lobes near the bottom of the map are the small domains of the molecule, the two helices running approximately vertically near the centre of the map are the C helices. A, A', coiled structure in the smaller domain, B, B', positions of tight intermolecular contact between small domains and a large domain of a neighbouring molecule.

imposed by least-squares minimization of differences in corresponding α -carbon positions, a subsequent rotation of the small domain of one subunit by 28° is required to bring it into coincidence with the small domain of the second subunit. The 'hinge' region of the molecule appears to consist of approximately four to five amino acids in the region connecting the C helix to the small domain. This kind of conformational difference between chemically identical subunits has been widely observed, such as in yeast hexokinase²⁴, tomato bushy stunt virus coat protein²², immunoglobulins²⁵ and alcohol dehydrogenase²⁶.

Interactions between the two subunits are through direct contact along virtually the entire length of the two C helices, and contact of the β -roll of one subunit with the central region of the C helix of the other. No direct contact between the two small domains is apparent.

Although the entire dimer does not possess an overall 2-fold axis, the two pairs of domains are each related by separate rotation axes. These two rotation axes have been obtained by computing the rotation required for least-squares minimization of the difference in corresponding α -carbon positions of each domain. The results are summarized in Fig. 3. The large domains appear to be related by 2-fold symmetry (computed rotation $179.2 \pm 1.1^\circ$), the small domains may have a small distortion from dyad symmetry (computed rotation $186.7 \pm 3.7^\circ$), the angle between the rotation axis relating the large domains and that relating the small domains is 13° . The extensive contact between large domains suggests that these two domains maintain the same relative orientation in the presence and absence of various ligands. The observed asymmetry is, therefore, probably generated by an alteration in the orientation of a small domain relative to the large domains.

Cyclic AMP binding

The electron density map contains density for two cyclic AMP molecules of equal and full occupancy per CAP dimer, as anticipated from data on cyclic AMP binding to CAP in solution²⁷. The cyclic AMP is completely buried within the interior of the β -roll of the large domain. The peak of highest electron

density in the cyclic AMP molecule and the entire map is presumed to be the phosphate. Further indication of the orientation of the nucleotide is provided by crystals soaked in a solution of 8-bromoadenosine-3', 5'-cyclic monophosphate (8-Br-cyclic AMP). The cyclic AMP seems to be oriented with the phosphate bound in the loop connecting strand 6 to strand 7 in the β -roll, with the nucleotide base in proximity of the two C helices. Whether the cyclic AMP makes direct contact with one or both of the C helices, and whether the two cyclic AMP molecules per dimer are bound identically cannot be determined conclusively at this stage. The finding²⁷ that cyclic AMP shows negative cooperativity in its binding to CAP in solution may explain the formation of the asymmetric dimer observed in the crystal.

CAP domain structure and function

The crystal structure of CAP shows that the subunits consist of two distinct structural domains which may be generally true for allosterically controlled gene regulatory proteins. Limited proteolysis studies of *E. coli* lac repressor²⁸⁻³⁰, bacteriophage λ repressor³¹ and CAP^{12, 13} suggest that these proteins have a small DNA-binding domain and a larger domain that binds allosteric effectors and/or holds the subunits together. In all three cases it now seems that there is little, if any, direct interaction between the two DNA-binding domains.

Proteolytic cleavage of the lac repressor in appropriate conditions yields two separate protein fragments^{29, 30}: a tetrameric core that binds inducers, and a smaller monomeric domain having 51-59 amino acids, depending on the protease used. The small domain retains nonspecific³⁰ and operator-specific³² DNA-binding activity but does not bind inducers. Similarly, proteolytic cleavage of the λ repressor yields a dimeric core devoid of DNA-binding activity and monomeric domains which bind both nonspecific and λ operator DNA³¹.

It has been demonstrated that limited proteolysis of CAP yields an amino-terminal fragment of subunit MW 12,500, which still forms dimers and binds cyclic AMP but has lost its cyclic AMP-dependent DNA-binding activity¹². Isolation of a second intact carboxy-terminal fragment and determination of its cyclic AMP- and DNA-binding activities have not been

Fig. 2 Schematic drawing of the CAP promoter in the closed conformation. The numbered arrows represent β -sheet, the lettered cylinders α -helices. The binding site for cyclic AMP in the β -roll is labelled. The dashed line circumscribes the region which is not well ordered in the electron density map.

Fig. 3 Schematic diagram of the molecular symmetry of the CAP dimer. The rectangles represent the large N-terminal domains, the triangles the small C-terminal domains.

reported. Nevertheless, by analogy with the *lac* and λ repressors one might presume that the small domain of CAP binds to DNA while the larger domain binds the cyclic AMP and forms dimers.

Interaction of CAP with DNA

It has not proved possible to observe DNA binding to these crystals. Crystals soaked in solutions containing short (6–10 base pairs) oligodeoxyribonucleotides become substantially disordered. Because the small domains form tight intermolecular contacts with a large domain of a neighbouring molecule (regions B and B', Fig. 1), the most plausible DNA-binding surface of the small domains is inaccessible to oligonucleotides. Thus, direct study of DNA binding in this crystal form is probably impossible. To determine experimentally the structure of CAP bound to DNA, it will be necessary to co-crystallize CAP with an appropriate oligo-DNA.

We have turned to model building to identify the DNA-binding site on CAP. Although we have not yet incorporated side chains into our CAP model, three general characteristics should be exhibited by the DNA binding site: (1) We expect a large degree of general structural complementarity between DNA and the potential binding site; (2) The correct CAP–DNA model must provide a structural basis for explaining the chemical protection^{33,34} and 'footprinting' (A. Schmitz, personal communication) data obtained on the CAP site of the *lac* operon; (3) Because the sequence of the CAP binding site at the *lac* promoter has a high degree of 2-fold symmetry, CAP probably binds to DNA with the approximate 2-fold axis that relates the two small domains coincident with the approximate 2-fold axis in the CAP site. Our conclusion is that the only model of interaction between a CAP dimer and DNA that adequately meets these three criteria requires that CAP binds to a left-handed, B-type DNA.

We have examined several possible modes of binding, and find only two ways in which a DNA molecule could interact with both small domains of a single CAP dimer with the approximate 2-fold axes of DNA and CAP coincident. Both ways involve the 22 Å-long F helices that are a dominant structural feature of the small domains, and are related by the approximate 2-fold axis between the small domains, are nearly parallel to each other and have their helix axes separated by about 34 Å. Furthermore, these helices are inclined at ~65–70° to the line connecting their centres.

The most complementary mode of interaction between the DNA and CAP is suggested by the 34 Å spacing and tilt of the 2-fold-related F α -helices. These two α -helices can fit snugly into two successive major grooves of left-handed B-DNA³⁵ (Fig. 4). In addition, the extended polypeptide chain is correctly positioned to interact with the sugar-phosphate backbone on either side of the two α -helices (Figs 4, 5c). Placing the α -helices in the major groove accounts nicely for the L8 and L29 mutations³⁶, methylation protection at the N⁷ of two pairs of guanines and the UV light-induced cross-linking of two symmetry-related thymines^{33,34}, because all these residues then interact with these helices (Fig. 5c). Furthermore, the phosphate moieties implicated by chemical modification to be interacting with CAP are almost all near the polypeptide backbone (Fig. 5c). In this way the protein can interact with at least 18–22 base pairs of DNA in a manner consistent with the footprinting data (refs 8, 34, 37 and A. Schmitz, personal communication) which show CAP protection spanning 25 base pairs.

Left-handed B-DNA has recently been shown to be a stereochemically acceptable conformation³⁵. Note that CAP cannot interact with left-handed Z-DNA^{38,39}, because the pitch is too large (45 Å) and there are no major grooves for the helices to fill. Furthermore, a purine–pyrimidine alternating sequence, requisite for formation of the Z-DNA helix, is not present in any known CAP recognition sites. Nevertheless, the known crystal

Fig. 4 Stereo drawing of the α -carbon backbone of the CAP dimer interacting with 22 base pairs of left-handed B-type DNA. One CAP subunit is drawn with dashed lines, the other subunit with solid lines. The coordinates for the DNA were derived from parameters given in ref. 37 and are presented in a space-filling representation using standard van der Waals radii. Note the extraordinary degree of general structural complementarity which extends over 18–20 base pairs (65–70 Å) of DNA.

Fig. 5 *a*, Sequence of the CAP-binding region of the *lac* operon. Boxes enclose regions of 2-fold symmetry in the sequence. *b*, Space-filling model of right-handed B-DNA, with proximal regions of the protein α -carbon backbone superimposed. Contact sites predicted from chemical modification studies^{33,34} are shaded. *c*, The same for left-handed B-DNA.

structure of left-handed Z-DNA and the stereochemical possibility of left-handed B-DNA suggest that the energy difference between left- and right-handed DNA may not be large and that stabilization of a left-handed DNA by a protein might be possible.

In contrast, a complementary interaction between CAP and right-handed DNA is not possible (Fig. 6). In this case the F α -helices are skewed relative to the major groove and make contact only with a portion of the sugar-phosphate backbone. No protein can project into either groove to make specific contacts. This model does not account for the methylation protection, mutations or cross-linking observed with bases in the major groove.

Structural rearrangements of CAP which would allow it to bind with its F helices in the major groove of right-handed B-DNA are highly implausible. Rotation of the F helices by 60–70°, while constraining their centre-to-centre distance at 34 Å, would be required. Rotation of the small domains about the hinge points changes the centre-to-centre spacing of the F helices and hence is excluded. Rotation of the individual helices by 60–70° about their centre points would maintain the 34 Å spacing, but would require a major refolding of the small domains. As the crystals are grown in the conditions in which CAP binds specifically to DNA in solution, we expect that the observed crystal structure is in the active DNA-binding conformation. By analogy with virtually all other known protein

examples, there is no reason to expect that the structure of CAP in the crystals differs significantly from its structure in solution.

The only other model of DNA bound to CAP that we seriously considered was right-handed B-DNA placed in the shallow depression formed primarily by the two parallel F helices (model not shown). In this model the long axis of the DNA runs parallel to the F helices and makes minor contacts with the proximal ends of the D helices. Such a model seems less plausible because (1) the length of protein contact along the DNA helix would be only 35 Å or 10 base pairs, (2) contact of CAP along the DNA phosphate backbone would be along alternate sides of the helix, rather than along one face, and (3) there would be no structural complementarity between protein and either the major or minor groove of DNA.

Thus, we conclude that only left-handed DNA, bound to CAP as shown in Fig. 4, accommodates all the relevant data. At least two experimentally verifiable predictions are made by this model. First, the inclusion of amino acid side chains in the protein model should provide a DNA-binding site which is complementary to left-handed B-DNA in hydrogen bond donors and acceptors and charge interactions, as well as in overall shape as shown here. Second, specific binding of active CAP to appropriate CAP sites should reduce the winding number in closed circular DNA by about four, although nonspecific binding of either active or inactive CAP would probably not. Both experiments are in progress.

A possible mechanism by which cyclic AMP might exert its allosteric effect on specific CAP binding to DNA is suggested by the model of CAP-DNA (Fig. 4) and the two different orientations of the small domains observed in the two subunits. If the removal of cyclic AMP changes the orientation of the small domain of one subunit relative to its large domain, then the DNA-binding site would be destroyed. It would not be unreasonable for the two subunits to have the same structure (either both 'open' or both 'closed') in the absence of cyclic AMP and the dimer a 2-fold symmetry axis. A ligand-induced change in relative domain orientation has been demonstrated in hexokinase²⁵ and alcohol dehydrogenase²⁶.

Formation of left-hand B-DNA could activate transcription initiation by RNA polymerase

We suggest that CAP activates transcription by destabilizing, or melting, a right-handed DNA helix within the promoter region. The significantly different positions of the known CAP-binding sites relative to the promoter in the *lac*^{33,34}, *gal*³⁷ and *ara*⁸ operons rule out the possibility of a unique protein-protein interaction between CAP and RNA polymerase. Also, the observation that inhibition of DNA gyrase activity *in vivo* inhibits the expression of catabolite-sensitive genes⁴⁰, and the more recent *in vitro* observation that in the *lac* operon, CAP stimulation of polymerase activity is most effective when the

Fig. 6 Stereo drawing of a model of CAP and right-handed B-DNA⁴⁵ in approximately the same orientation as in Fig. 4. In this figure the DNA has to be moved further from the protein to avoid overlap of the F helices and the sugar-phosphate backbone. The contact surface between these macromolecules is strikingly less than in Fig. 4.

promoter and CAP site are in negatively supercoiled rather than relaxed linear DNA (W R McClure, personal communication), demonstrate that CAP is most effective when it is energetically favourable to unwind, and remove negative supercoils from a closed circular DNA helix⁴¹

Thus, although we do not know specific details of the transition, we propose that CAP traps specific regions of DNA in a left-handed helical conformation, and that the right-to-left helix transition denatures nearby regions of the helix in the promoter⁴², possibly the region specifically unwound by RNA polymerase itself⁴³

Anderson, Ohlendorf, Takeda and Matthews⁴⁴ have recently determined the course of the polypeptide backbone of λ cro protein and find that this repressor protein has two α -helices separated by 34 Å that can fit well into the major groove of right-handed B-DNA

These data suggest the following general model for proteins that regulate gene transcription (1) Two DNA-binding domains related by (approximate) 2-fold symmetry bind to one side of the DNA helix at the site of (approximate) 2-fold symmetry (2) Base-specific recognition can be accomplished by α -helices of the protein binding in the major groove of B-type DNA (3) Repressors, by binding to right-handed B-DNA, stabilize the right-handed helix and act as 'anti-melting' proteins, CAP protein, by binding to a left-handed helix, destabilizes the helix and facilitates binding and initiation by RNA polymerase

Arrangements and rearrangements of sequences flanking the two types of rDNA insertion in *D. melanogaster*

Heli Roiha, J. Ross Miller, Lesley C. Woods & David M. Glover

Cancer Research Campaign, Eukaryotic Molecular Genetics Research Group, Department of Biochemistry, Imperial College of Science and Technology, London SW7 2AZ, UK

The two types of Drosophila melanogaster rDNA insertion occur at different sites in the 28S gene, separated by 51 nucleotide pairs. A short segment of rDNA is deleted at the site of the 5 kilobase type I insertion, whereas there is no such deletion of rDNA sequences which flank the type II insertion. Type I insertion elements in tandem arrays are flanked by very short segments of the 28S rRNA gene

A LARGE proportion of the ribosomal genes of *Drosophila melanogaster* contain an intervening sequence in the 28S rRNA gene¹⁻⁴. There are two types of intervening sequence which have been termed the type I and type II insertions. The type I insertions are found in about 60% of the rDNA units of the X chromosome⁵⁻⁷ and the type II insertions in about 15% of the rDNA units of both the X and Y chromosomes^{6,8-10}. Physical mapping studies showed that these two non-homologous types of insertion are apparently located within the rDNA at identical sites, suggesting that there might be a structural feature of this region which could promote either the acquisition or loss of these elements. A high proportion of type I sequences is also

present in the chromocentral heterochromatin^{7,11}, linked together in tandem arrays¹². As far as is known, the type II insertions are only found in ribosomal gene repeats.

Intervening sequence elements have subsequently been reported in the distal part of the gene for the large rRNA of several other organisms¹³⁻¹⁸. The nucleotide sequences at the junctions between the gene and the intervening sequence have been determined for the 28S gene from *Tetrahymena*¹⁹, the chloroplast rDNA from *Chlamydomonas*²⁰ and the mitochondrial rDNA of yeast²¹. In none of these cases is it possible to recognize a consensus sequence which might serve as a recognition site for enzymes which process the primary rRNA

Fig 1 Sequencing strategies. The physical maps presented show cloned fragments of chromosomal DNA which contain representative arrangements of the rDNA insertion sequences. Subcloned fragments of these DNAs which contain the junction of the insertion sequences with their flanking sequences are shown beneath each map. The construction and isolation of the original genomic clones cDm103³¹, cDm219¹², cDm264¹⁰ and cDm207⁸ have been described elsewhere. The *D. melanogaster* DNA in pDm238 originates from the same set of randomly cloned segments as cDm219, cDm264 and cDm207, except that in this case a 12-kilobase *EcoRI* fragment from the original clone has been subcloned into the plasmid pBR322. All the subclones described were constructed in the appropriate sites of pBR322 as previously described¹². The exceptions are p238BH1 and p103BH1, in which the vector is pAT153³³, a non-mobilizable derivative of pBR322. The restriction site symbolized as *Bam*HI/*Bgl*II represents the product of ligating *Bam*HI and *Bgl*II termini in the vector and the *Drosophila* DNA, respectively. Only those restriction endonuclease cleavage sites used for either subcloning or sequencing are shown. The arrows beneath the maps of the subclones indicate the extent and direction of the sequences read from various restriction sites. All sequencing was performed using the techniques of Maxam and Gilbert³⁴. In each of the maps of the original clones, the ribosomal genes are indicated by filled blocks, the type I insertions by horizontal hatching and the type II insertion by dotted shading. These regions are not indicated in the subclones. The plasmid vectors are indicated by cross-hatching.

transcript, such as has been postulated for genes transcribed by RNA polymerase II²². Contrary to these cases, it is not certain whether those genes from *D. melanogaster* which contain the type I insertion sequence are transcribed into functional rRNA, as full-length transcripts corresponding to the gene and intervening sequence are extremely rare²³ and furthermore, there are rDNA units within the genome which do not contain intervening sequences.

We describe here the nucleotide sequences of the junctions between rDNA and the insertions and show that the two types of insertion occur at sites which are 51 nucleotides apart. The type I insertion occurs at an analogous site to the insertion in *Drosophila virilis* rDNA^{24,25}, but in all our clones we find that by comparison with the *D. virilis* sequence, 22 nucleotides of rDNA are deleted to the left-hand side of the insertion. There is no such deletion in the rDNA sequences flanking the type II

Fig 2 Sequence of a 497-nucleotide segment of the 28Sβ gene. This sequence was primarily obtained from p238BH1, a subclone of an uninterrupted unit of rDNA (see Fig 1). Plasmid DNA was labelled for sequencing either at the *Hin*dIII site by 'filling in' the cohesive terminus using reverse transcriptase or at the *Hae*III site using terminal transferase-mediated addition of an α -labelled ribonucleotide³⁴. The sequence of the equivalent regions in cDm103 and cDm264 have also been determined using comparable labelling techniques (see Figs 3 and 6 legends). Other than a short deletion of rDNA sequences, β'' , in cDm103 (see text) there are no differences in the segments of rDNA which have been sequenced in these plasmids. The two 'halves' of the 28Sβ gene on either side of the insertion are termed β 1 and β 2. We have arbitrarily begun our numbering from the position of the type II insertion which is marked with an arrow. In 28Sβ genes containing the type I sequence, the β'' segment is substituted by the insertion. The β^* sequence is analogous to a segment of rDNA which is duplicated in *D. virilis* rDNA units containing insertions²⁵, and which is also present in the clone cDm219. The β'' segment is also present in cDm219 whereas β' and adjoining β 1 sequences are not. The division of the 28Sβ gene into these units is to facilitate comparisons between various plasmids and does not necessarily denote any functional significance of these regions. The arrow marked Tp indicates the position of the intervening sequence in a homologous region of the 28S gene of *Tetrahymena pigmentosa*¹⁹.

Fig. 3 Comparison of the junctions of the type I insertion in *D. melanogaster* rDNA with those of the insertion in *D. virilis* rDNA. The *D. virilis* sequence shown is taken from Rae *et al.*²⁵ The sequences at the junctions of the type I insertion of cDm103 were obtained from the subclones pC4, pC25 and p103BH1 labelled by a 'filling-in reaction' with reverse transcriptase. The extent of the sequence determined for the Dm103 insertion in these experiments is indicated in Fig. 4. Segments of the 28S β gene are indicated above the boxed-in sequence and the insertion sequence is italicized.

insertion. The chromocentral type I insertion elements occurring in tandem arrays are separated by short DNA segments identical to parts of the 28S gene which flank the type I insertion in rDNA. We also analyse the structure of a segment of rDNA which has a 28S gene containing both types of insertion.

Location of insertions in the 28S rRNA gene

The 28S rRNA of *D. melanogaster* consists of four polynucleotide chains—the 2S RNA, 5S RNA, 28S α RNA and 28S β RNA—which are held together by hydrogen bonding. The relative positions of the DNA coding for these molecules are shown on the physical map of pDm238, a cloned rDNA unit which does not contain an insertion sequence (Fig. 1). The positions of type I and type II insertion sequences within the 28S β gene can be seen on the maps of the cloned segments cDm103^{1,2} and cDm 264¹⁰, respectively. The insertions divide the gene into two regions which have been termed 28S β 1 and 28S β 2 (Fig. 1). We have subcloned a restriction fragment from the uninterrupted unit pDm238 which contains the sites for the insertions, and restriction fragments from cDm103 and cDm264 which contain the junctions between the 28S β gene and the two insertion types. Figure 1 also shows restriction maps of these subcloned fragments and the DNA sequencing strategy which we followed to obtain a precise localization of the insertion elements within the gene.

The sequence of the 28S β gene in the vicinity of the insertions is given in Fig. 2. The sites of the insertion elements are evident by comparing this sequence with that of the comparable regions from cDm103 and cDm264 (see below). The two types of insertion occur at different sites within the 28S β gene, separated by 51 base pairs. The type II sequence is located at a site just five residues away from the position of the intervening sequence in the 28S gene in some strains of *Tetrahymena*¹⁹. The type I sequence is found at an analogous position to the insertion in the rDNA of *D. virilis*²⁵. The sequence of this same region in *D. virilis* is highly homologous and shows only a few single-base differences with the *D. melanogaster* rDNA.

Fig. 4 Type I insertions. The continuous sequence from the junction of units 3 and 4 from cDm219 (Fig. 1). The two short segments of rDNA sequences β^* and β^{11} shown in boxes, occur at this junction (see text). Nucleotides 0 to -226 are from the right end of unit 3 and 0 to +337 are from the left end of unit 4. Sequencing was performed from the indicated *Hind*III and *Bst*I sites labelled at 5' termini using polynucleotide kinase and [γ -³²P]ATP (Fig. 1). A comparison is also given of type I sequences from cDm103 and cDm207 determined as indicated in the legends to Figs 3 and 6, respectively. Only the differences between these sequences and that of Dm219 are indicated. Δ Indicates a deleted nucleotide. The extent of the sequence determined for these clones is indicated by brackets. The right-hand end sequence of the Dm103 insertion comes from the subclones pC25 and pC4 and extends into the β^2 region of the 28S gene. The left-hand sequence of the cDm103 insertion is from p103BH1 and extends into the 28S β 1 region. The left-hand sequence of the cDm207 type I sequence is from p207RH16 (see Fig. 6).

Differences between the junctions of the major insertion in

D. melanogaster and *D. virilis*

Rae *et al.*²⁵ have demonstrated that in *D. virilis* rDNA a 14-nucleotide sequence present only once at the site of the insertion in the uninterrupted rDNA unit is repeated on both sides of the insertion. We find that the type I insertion in cDm103 is at this same site, flanked on its right-hand side by the same 14-nucleotide sequence as found in *D. virilis* which we have called β^* (Fig. 2). The structure of the left-hand side differs from that of *D. virilis*. There is no β^* sequence and, furthermore, there is a deletion of nine residues of rDNA which we have called the β''' segment (Fig. 3).

The arrangement of the β^* sequence in *D. virilis* resembles that found at the insertion sites of transposable elements of both prokaryotic²⁶ and eukaryotic^{27,28} organisms. The occurrence of an insertion at the same site in *D. melanogaster* suggests that if the insertions arose in the rDNA of ancestral Dipteran species as a result of transposition, then the resulting unit has been reasonably stable throughout evolution. Alternatively, the duplication of the β^* sequence may be analogous to the duplication of *att* site sequences resulting from homologous recombination which occurs between the genomes of *Escherichia coli* and its lambdoid phages²⁹. In this case site-specific recombination would perhaps be a continuous process in the rDNA of *Drosophila* species. The deletion of rDNA sequences from the left-hand side of the *D. melanogaster* insertion is also analogous to the type of deletions that can be generated on excision of either prokaryotic transposable elements or lambdoid prophage. Although rDNA units containing such deletions are clearly stably maintained to some extent within the genome it remains of interest to know whether there are rDNA units within *D. melanogaster* which have the duplicated segments found in *D. virilis*. This would help answer some of the above questions.

Small rDNA segments occur in the chromocentral type I sequences

As many as 50% of the type I sequences are not inserted into rDNA but are located within the chromocentral heterochromatin and also at a single site on chromosome 4 in band 102C^{7,12}. The cloned DNA segment cDm219 originates from the chromocentral heterochromatin and contains five discrete units of the type I sequence arranged in tandem. We have determined the sequences between the junctions of the units of cDm219 following the strategy outlined in Fig. 1. The sequence at the junction of units 3 and 4 of the tandem array is given in Fig. 4, where the sequences corresponding to the left- and the right-hand ends of the rDNA insertion have positive and negative numbers, respectively. At the left hand of these units we find

Fig. 5 A schematic comparison of the segments of the 28S β gene which flank the type I insertions in cDm103 and cDm219 with those flanking the insertion in *D. virilis* rDNA.

20 nucleotides of rDNA, the β'' segment, the same segment of the 28S β gene which flanks the left hand of the type I insertion in rDNA (Fig. 3). At the right-hand end of these units the β^* segment flanks the insertion as in Dm103 (Fig. 3), and at the junctions between the tandemly arranged units of cDm219 the β'' segment is linked to the β^* segment. The relative positions of these small segments of the 28S β gene which flank the type I insertion of *D. melanogaster* rDNA and the insertion in *D. virilis* rDNA are shown schematically in Fig. 5. The finding of short segments of rDNA which flank units of chromocentral type I sequences strongly suggests that type I elements can be transposed from the nucleolus and that co-transposition of adjoining rDNA segments can occur during this process. The excised unit could then be amplified either by autonomous replication or by unequal exchange following integration into its new chromosomal site. If the insertion elements of both *D. virilis* and *D. melanogaster* are indeed mobile, these observations would suggest that only the right-hand β^* element is required for transposition. Perhaps it is significant in this respect that within the rDNA sequence to the right of β^* in both *D. virilis* and *D. melanogaster* there is a direct duplication of part of the β^* sequence (residues 66–79, Fig. 2).

The continuous sequence given in Fig. 4 is that of the junctions of the cDm219 subclones pB2 and pB7. We have also sequenced about 200 residues on either side of the junctions in other subcloned type I units of cDm219, and have found no differences between these junctions and the sequence shown in Fig. 4. Figure 4 also compares the sequences from the left and right ends of the rDNA insertion in cDm103. Within this limited sequence there seems to be a significant difference in the degree of conservation between the left and right ends of these insertion elements. The only base difference within a comparable 226-nucleotide sequence from the right-hand end is the presence of an extra dA residue in cDm219. At the left end, however, there are 19 nucleotides which differ within a comparable 231-nucleotide sequence. There is similar variability in an equivalent sequence from the left-hand end of the type I insertion found in cDm207 (see below), this sequence has 10 single-base differences when compared with this Dm219 element and 20 compared with cDm103. There is also a 22-nucleotide deletion in this region of cDm207. In this respect, we note that although there is considerable length variation of the type I sequences, it is the sequences from the right-hand side of the unit which are preserved^{3,6}. It will be interesting to examine the nature of junctions of these shorter type I elements with adjoining rDNA.

Junctions of the type II insertions

About 15% of the *D. melanogaster* rDNA units have insertions with cleavage sites for *EcoRI*^{6,8}. We have characterized several cloned segments of rDNA containing complete type II sequences and find no homology with the type I sequences¹⁰. We chose to determine the sequence at the junctions of the type II insertion of cDm264 because this insertion has the most commonly observed length and restriction endonuclease cleavage pattern. We find that there is a direct sequence repeat at the left-hand junction of the type II insertion with the 28S β gene. The repeated sequences, GGGGAG, are contiguous and are formed partly from rDNA sequence and partly from insertion sequence (Fig. 6a). This is quite distinct from the duplication of the β^* sequence flanking the *D. virilis* insertion. The right-hand junction of the type II insertion shows a striking tract of 22 dA residues, which are followed by the β' , β'' , β''' , β^* and β^2 segments of the 28S gene (Fig. 6b, c). Unlike the case of rDNA containing the type I insertion, there is no deletion of adjacent rDNA sequences.

The deletion in Dm103 makes it extremely unlikely that units of this type are ever used in the production of mature rRNA. This is in accord with the findings that large nuclear transcripts containing type I sequences are extremely rare, and that the most abundant transcript is a cytoplasmic molecule of 1 kilobase, present in about 50 copies per cell²³. Choori³⁰, however, has described the presence of long transcription units in actively

Fig 6 Sequences at the junctions of the type II insertions within rDNA. *a*, The sequence of the left end of the type II sequences in cDm264 and cDm207 comes from the subclones p264BS21 and p207BS2, respectively. The restriction fragments were labelled at the *Sall* site by 'filling-in' the *Sall* cohesive end using reverse transcriptase. Only the regions in which the cDm207 sequence differs from the cDm264 sequence are shown. *b*, The sequence of the right end of the type II sequence in cDm264 and cDm207 from the subclones p264RH23 and p207RH16, respectively. *Hind*III and *Hinf* termini were 3'-labelled using reverse transcriptase and the *Hae*III termini 3'-labelled using terminal transferase. The single bases of the cDm207 sequence which differ from cDm264 are indicated. *c*, Schematic diagram of how these rDNA segments differ to the right of the type II insertion. The segments β' and β'' , defined in Fig 2, are found in each plasmid. In cDm264, β' is contiguous with the remainder of the 28S β gene, whereas in cDm207 it is linked to the left end of the type I sequence. This type I sequence in cDm207 differs from those of cDm219 and cDm103 at the sites indicated in Fig 4.

transcribed chromatin which could represent transcription of rDNA units containing insertions. The distribution of these long transcription units correlates with the distribution of type II sequences in the rDNA of the X and Y chromosomes. It is possible, therefore, that rDNA containing type II insertions has a similar transcriptional pattern to that found in *Tetrahymena* rDNA where the insertion sequence is present in the primary transcript and is subsequently removed. Moreover an A+T-rich region seems to be a common feature of the right-hand junction of the insertions in the rDNA of *Tetrahymena*¹⁴, *Chlamydomonas* chloroplasts²⁰ and yeast mitochondria²¹, for which the A+T content of the rightmost 25 nucleotide pairs is 72, 80 and 76%, respectively. Indeed, it has been postulated that A+T-rich regions might be an important feature of other processing sites in ribosomal transcripts.

A 28S β rRNA gene containing both insertions

We have previously found that the clone cDm207 contained both types of insertion and that within our mapping resolution the junction of type II with type I sequences corresponded to the right and left ends of these respective sequences, as they are found singly within rDNA¹⁰. Nucleotide sequencing indicates that the type II element occurs at exactly the same site as in cDm264 (Fig 6*a, b*). Interestingly, the type II sequence in cDm207 differs from that of cDm264 by an additional 23 nucleotides which occur between the two repeated hexameric sequences. A tract of 19 dA residues occurs at the right-hand end of the type II insertion in cDm207. However, it is linked to only 51 nucleotides of rDNA, corresponding to the β' and β'' segments, which intervene between the sites of the two insertions. The junction between the β' segment and the type I insertion is identical to that found in cDm103 and in the units of cDm219. The comparative structures of cDm207 and cDm264 are indicated schematically in Fig 6*d*.

We previously noted that the restriction map of the type I insertion in cDm207 is more similar to that of a Dm219 unit than of the Dm103 rDNA insertion. A sequence comparison within a limited segment of these DNAs is consistent with this observation (see above and Fig 4). The chromosomal segment Dm207 also contains an unusual interruption of the internal transcribed spacer region (see Fig 1), and this has previously led us to propose that it was the product of a recombinational event between an rDNA unit containing type II sequences and type I sequences elsewhere in the genome. That recombinational events occur to produce rDNA segments containing both types

of insertion is to be expected because the insertions occur at different sites. Several such clones have been isolated by ourselves and others and we expect that sequencing will show such clones to have analogous organizational features to those which occur between the two types of insertion in Dm207.

This work was supported by project grants from the MRC. D M G holds a career development award from the Cancer Research Campaign. We thank Simon Kidd for his interest in this work, for providing us with data on the positioning of restriction endonuclease cleavage sites and for the construction of several of the subcloned plasmids described here. We also thank Therese Anderton for help with sequencing techniques and Sue Hayman for typing the manuscript, especially the figures.

Note added in proof We have recently sequenced the junctions between rDNA and a 1.0 kilobase type I insertion. This insertion is flanked by duplicated β^* segments and there is no deletion of rDNA sequences.

The three-dimensional structure of the 66-amino acid cro repressor protein of bacteriophage λ suggests how it binds to its operator DNA. We propose that a dimer of cro protein is bound to the B-form of DNA with the 2-fold axis of the dimer coincident with the 2-fold axis of DNA. A pair of 2-fold-related α -helices of the repressor, lying within successive major grooves of the DNA, seem to be a major determinant in recognition and binding. In addition, the C-terminal residues of the protein, some of which are disordered in the absence of DNA, appear to contribute to the binding.

INTERACTIONS between proteins and nucleic acids are of central importance in molecular biology. Some proteins bind single-stranded polynucleotides while others recognize double-stranded ones. None of these interactions is well understood in molecular terms. In particular, the way in which proteins recognize specific base sequences within double-stranded DNA has remained enigmatic.

The cro protein from bacteriophage λ (hereafter called 'cro') is a repressor molecule which recognizes and binds tightly certain sequence-specific operator regions within the DNA of the bacteriophage. Cro is the smallest repressor protein that has been characterized, and is of interest both because of its role in the delicately balanced regulatory system of bacteriophage λ , and as a general model for protein-DNA interaction.

We describe here the three-dimensional structure of the cro repressor and its apparent mode of interaction with operator DNA. The postulated interaction between repressor and operator is consistent with a variety of chemical and genetic evidence, and may provide a general model for the interaction of proteins with helical DNA.

The bacteriophage λ genome encodes two repressor proteins that play essential, contrasting parts in regulating the development of the phage. The product of the cI gene, the cI or λ repressor ('cI'), is required for the maintenance of the lysogenic state, whereas the product of the cro gene is necessary during the lytic cycle of phage development (for reviews see refs 1-4, 33, 34). Both the cro and the cI repressors compete for and bind two operator regions within the phage genome. These operator regions each consist of three binding sites for the repressor molecules, and the respective repressors have different relative affinities for each of the sites within the operator regions^{5,6}. The use of these binding sites by cro and cI provides for a switch between the lysogenic and lytic pathway. The cro/cI interaction is the clearest example of such a developmental switch³³ and the structural results presented here begin an understanding of this switch at the molecular level.

The cro protein is well characterized^{7,8}. It is a small basic protein 66-amino acid residues long, with a monomer molecular weight of 7,351. Both the amino acid sequence of the protein⁹ and the nucleotide sequence of the cro gene have been determined¹⁰.

Structure determination

The structure was determined by the method of isomorphous replacement¹¹⁻¹³. Protein purification and crystallization from 1.1 to 1.3 M phosphate were as described previously^{8,14}. The space group is R32 and the cell dimensions in the hexagonal system $a = b = 91.9 \text{ \AA}$, $c = 268.9 \text{ \AA}$.

Potential heavy-atom derivatives were initially screened by precession photography, and, later, by using a diffractometer to collect 5- $\text{\AA}$ -resolution data sets. The first heavy-atom derivative to be interpreted was obtained using PtCl_4^{2-} and was initially solved by a 'brute force' approach in which all possible indi-

vidual sites, and then combinations of sites, were explored (ref 15 and unpublished results of B W M). Using the phases obtained from this platinum derivative, other potential derivatives were then evaluated in the normal way^{12,13}. In the end, five derivatives were selected for high-resolution data collection (Table 1). All the derivatives have multiple binding sites, as expected with multiple copies of the protein present in the crystallographic asymmetric unit (see below). Higher-resolution data were collected by oscillation photography¹⁶ which permitted collection of data sets to a nominal resolution of 2.8 $\text{\AA}$ or better from a single crystal. The crystals often grow as long triangular prisms¹⁴, in which case they can be translated between series of exposures. Some data collection statistics are included in Table 1.

Two preliminary electron density maps to 5 $\text{\AA}$ resolution were calculated, one using the data collected by diffractometry, and the other using a subset of the higher-resolution oscillation data. The two maps were quite similar, and, as discussed below, were important in working out the arrangement of the cro monomers within the crystallographic asymmetric unit.

Molecular symmetry

The initial analysis of the cro protein crystals showed them to contain multiple copies of the protein in the asymmetric unit. On the basis of the density measurement of two cross-linked crystals, there seemed to be six monomers, that is, three dimers, per asymmetric unit¹⁴. However, examination of the 5- $\text{\AA}$ -resolution electron density map revealed that there were four monomers per asymmetric unit, not six. The error in the previous estimate could be due either to the presence of the cross-linking agent or to errors in density due to the limited amount of material available.

We attempted to determine the relation between the monomers in two ways—by inspection of the 5- $\text{\AA}$ -resolution electron density maps, and by consideration of the relation between the sites of heavy-atom binding. Initial inspection of the 5- $\text{\AA}$ -resolution map revealed an obvious 2-fold symmetry.

Table 1 Heavy-atom derivatives

Derivative	No of sites	R_{Merge} (%)	R_{Der} (%)	Reflections above 3σ	R_{wc} (%)	$\langle f_{\text{H}} \rangle$	E
Native	—	9.5	—	9184	—	—	—
PtCl_4^{2-}	6	9.6	14.5	5068	30.5	64.3	54.5

Overall figure of merit¹⁸ to 2.8 $\text{\AA}$ resolution, 0.45. $R_{\text{Merge}} = 100 \sum (I_i - \langle I \rangle) / \sum \langle I \rangle$, $R_{\text{Der}} = 200 \sum |I_{\text{PH}} - I_P| / \sum (I_{\text{PH}} + I_P)$, $R_{\text{wc}} = 100 \sum \omega |F_{\text{PH}} - F_P| - f_{\text{H}}| / \sum \omega |F_{\text{PH}} - F_P|$ (f_{H} is the mean heavy-atom scattering, E the average lack of closure for centric reflections¹⁸). EMTS, ethyl mercury thiosalicylic acid. Hg^{2+} data set collected by precession photography.

Fig. 1 Corresponding electron density sections through each of the four cro molecules in the crystallographic asymmetric unit, transformed into a common coordinate frame. Clockwise from top left the density is for molecules O, A, B and C, with the averaged density below α -carbon atoms within ± 2.5 Å of the section are indicated by the solid circles

axis lying approximately in the plane $z = 1/12$. This 2-fold axis also related, in pairs, most of the major heavy-atom sites. Further analysis of the 5-Å map, facilitated by the use of an MMS-X computer graphics system¹⁷, suggested that there were two additional 2-fold axes inclined to the first. The positions of these local symmetry elements were confirmed by calculating correlation coefficients between the electron density of the individual monomers, rotated and translated to superimpose one monomer on another (Table 2). The four monomers are related in pairs by mutually perpendicular intersecting (or nearly intersecting) 2-fold axes. In other words, the four monomers are arranged in the crystal with local 222-point symmetry. The symmetry of the molecules in the crystal does not itself imply anything about the state of aggregation in solution. In principle, the protein could exist as individual monomers, as dimers with 2-fold symmetry, or as tetramers. However, the specific interactions which we observed between the four monomers (see below) suggests that cro may exist in solution as a tetramer. The extent to which the molecular arrangement may depart from exact 222 symmetry, and the potential biological relevance of such deviations from exact symmetry, remain to be determined.

Most, but not all, of the heavy-atom sites are related to each other by the 222 local symmetry elements. For each 2-fold axis, related pairs of sites can be superimposed within ~ 1.9 Å (Table 2). Although the 2-fold symmetry was used as an additional check in the interpretation of the heavy-atom derivatives, it was not imposed on the heavy-atom coordinates.

The electron density map

An electron density map was calculated to a nominal resolution of 2.8 Å using the five heavy-atom derivatives described in Table 1 (ref. 18). Although the phase angles are well determined to about 3.5 Å resolution, their accuracy at higher angles is limited by the scattering intensity of the derivative crystals, which becomes very weak at higher resolution, and also, in part, by non-isomorphism.

To improve the accuracy of the electron density map and facilitate its initial interpretation, the density of the four monomers in the asymmetric unit was averaged (Table 2, Fig. 1). If the assumed transformations are correct and all four monomers are, in fact, identical, the averaging process should improve the accuracy of the electron density map. In practice, the averaging process clearly improved the overall 'cleanliness' of the map, but also resulted in a loss of detail and reduction in the effective resolution (Fig. 1). Presumably, application of more sophisticated averaging techniques¹⁹ and refinement of the individual monomers will lead to a more precise description of the structure.

The averaged electron density map was displayed both as a 'mini-map' and on a scale of 2 cm = 1 Å in an optical comparator^{20,21}. Several helices and a region of β -sheet were immediately apparent, and the course of the polypeptide backbone could be readily followed from one end to the other. The direction of the polypeptide chain was initially deduced from the observation that the major platinum binding site was at a position 12 residues from one terminus, obviously corresponding to Met 12. From this point the known amino acid sequence of the protein^{9,10} could be compared with the electron density map. Although the interpretation of the electron density map is fully consistent with the sequence, note that the limited resolution of the current map, together with the averaging process described above, results in poorly defined density for the respective side chains. The backbone density is strong and unambiguous from the amino terminus to residue Lys 62, but at this point the density becomes very weak, indicating that the four carboxy-terminal residues are disordered in the crystals. This appears to be the case for each of the four cro monomers.

Conformation of the cro repressor

The conformation of a cro monomer is illustrated in Fig. 2. The structure is very simple, consisting of three strands of antiparallel β -sheet (residues 2–6, 39–45 and 48–55), and three α -helices (residues 7–14, 15–23 and 27–36). As described below, the C-terminal residues form an extended 'arm' (Fig. 2) which interacts with another monomer and seems to participate in DNA binding.

The detailed arrangement of the four repressor monomers in the crystals is shown in Fig. 7. The respective local 2-fold symmetry axes relating the monomers are designated P, Q and R, and the monomers themselves O ('original'), A, B and C (Table 2). It has been assumed for some time that the cro

Fig. 2 Backbone of monomer O of the cro repressor protein. As discussed in the text, the four C-terminal residues 63–66 are disordered. The local orthogonal 2-fold symmetry axes P, Q and R relate the molecule shown to monomers A, B and C, respectively.

Fig. 3 DNA operator O_{R3} , drawn in the B form (after Ptashne *et al.*⁴) Ethylation of the phosphates, labelled P, hinders cro repressor binding, binding of cro protects the N^7 positions of guanines, labelled G, from methylation by dimethyl sulphate. The figure is based on experiments of Johnson, Ptashne and collaborators.^{4,5,35}

repressor exists as a dimer in physiological conditions⁸. Therefore, we expected the four cro monomers in the crystal to consist of two dimers. However, inspection of the molecular packing does not obviously support this assumption. The monomers O and B (and, similarly A and C) are related by the Q axis, and have extensive interactions between their C-terminal arms, each of which lies against, and is, in part, hydrogen bonded to, its 2-fold-related partner. It seems likely that this interaction persists in solution. However, there are also specific interactions about the R symmetry axis, where the polypeptide backbone of one monomer hydrogen bonds to the 2-fold-related backbone of the other monomer so as to expand the three-strand β -sheet of the monomer into a six-strand antiparallel sheet in the dimer. In addition, the amino terminus of monomer O is linked by an ionic interaction to Glu 53 of monomer A, with similar interactions for the other amino termini. The four amino-terminal methionines are grouped together and participate in a distinct hydrophobic region at the centre of the cro tetramer. Thus, although the packing arrangement seen in the crystal does not prove that cro exists as a tetramer in solution, it does suggest this. Whether cro exists as a dimer or tetramer has no bearing on the proposed model for DNA binding.

Interaction of cro with DNA

Both cI and cro repressors compete for three sites within the left and the right operators of bacteriophage λ . In the right operator there are three binding sites (O_{R1} , O_{R2} and O_{R3}) each consisting of 17-base pair regions separated by spacers of 6 or 7 base pairs²². The sequences of the three 17-base pair regions are similar to each other, but not identical, and, in addition, the sequence within each region is approximately symmetric. Mutations within the 17-base pair regions reduce the binding affinity of both cro and cI, whereas mutations in the spacer regions have no effect on binding (refs 4, 6, 23, 24 and refs therein). Chemical probe experiments^{4,5,35} indicate that both cro and cI repressors bind primarily along one face of the DNA double helix and protect many of the same groups. The results of such experiments for cro binding to O_{R3} are illustrated in Fig. 3. Methylation by dimethyl sulphate of the N^7 of six guanines in the major groove is prevented by the presence of cro, but

methylation of N^3 of adenine, exposed in the minor groove of the DNA, is not prevented. Furthermore, ethylation of any of the six phosphates shown in Fig. 3 interferes with cro binding⁴. The pattern for cI is very similar, but is slightly more extended, and includes four additional phosphates. Such experiments suggest that both cro and cI contact the DNA in the major, but not the minor, groove^{4,5}. Furthermore, it seems likely that both repressors bind to the DNA with two symmetry-related subunits of the protein in contact with the two symmetry-related halves of the operator, and the 2-fold axis of the protein coincident with the 2-fold axis of the DNA. In this way the complex of bound repressor and operator would have a common 2-fold symmetry axis. There would, of course, be slight deviations from exact 2-fold symmetry because of the inexact symmetry of the DNA base sequence, and also, possibly, due to the protein.

To determine possible modes of binding of cro to DNA, we looked for a feature of the cro monomer which, together with its 2-fold related mate, would form a structure complementary to that of the operator DNA, and which, when aligned on the DNA, would be consistent with the protection experiments summarized in Fig. 3. An obvious candidate is the helix from residues Gln 27 to Ala 36. This helix lies along the surface of the protein, with isoleucines 30 and 34 contributing to the hydrophobic interior of the monomer, but with the helix otherwise protruding from the surface of the protein (Fig. 2). The corresponding helix in monomer B, related by rotation about axis Q (Fig. 4) is parallel, and the respective helices have a centre-to-centre distance of 34 Å, the same as the separation between successive major grooves of B-form DNA (Fig. 3). Furthermore, the angle made between the axes of the two α -helices and the line connecting their midpoints is equal to the angle between the major groove of the DNA and its long axis (Figs 3, 4). The sense of the respective angles is such that the two helices can be accommodated, in a very natural way, within successive major grooves of DNA in its normal Watson-Crick B conformation^{25,26}.

This hypothetical arrangement was checked by fitting a model of the cro molecule to that of DNA. We required that the 2-fold axis relating the cro monomers had to coincide with the 2-fold axis through the centre of the DNA operator. Thus, the fitting of cro to the DNA is very restrictive, allowing only two degrees of freedom—one a rotation of cro relative to the DNA, about the common symmetry axis; the second a translation of cro along the symmetry axis, which varies the distance between cro and the long axis of the DNA. The results of this first, albeit crude, fitting process are shown in Figs 5, 6 and 7.

The complementarity between protein and DNA is striking. In addition to the overall correspondence between the respective backbones of the DNA and protein, residues Ser 28, Ala 29, Asn 31, Lys 32, Ala 33 and His 35 of the above-mentioned α -helix are in a position to interact either with the exposed hydrogen bonding groups of the major groove, conferring specificity, or with the negatively charged phosphates, promoting generalized binding. Nearby residues, including Arg 38 and Lys 39, are also suitably located to contribute to binding and recognition. Close to the 2-fold symmetry axis, the sequences Glu 54–Val 55–Lys 56 of the two monomers form a pair of antiparallel β -sheet strands parallel to the minor groove which possibly interact with the DNA in the manner proposed

Table 2 Relations between the four cro monomers

Symmetry axis	Pairs of heavy-atom sites	r m s error in heavy-atom sites	Monomers related	Electron density correlation
P	26	1.80	O,A	0.58
Q	26	1.97	O,B	0.54
R	25	1.94	O,C	0.55

$C_{ij} = \sum \rho_i \rho_j / (\sum \rho_i^2 \sum \rho_j^2)^{1/2}$ where the summations are over all values, ρ_i , of the 2.8 Å-resolution electron density map within 15 Å of the centre of the respective monomers.

Fig. 4 Dimer of two cro molecules viewed along the Q symmetry axis. The P and R symmetry axes are also shown. Regions of the protein backbone closest to the viewer, and presumed to interact with DNA, are drawn solid. These regions include two α -helices, 34 Å apart, inclined at 32°, and also a pair of extended strands close to the Q-axis.

by Church *et al.*²⁷ The four C-terminal residues of the 2-fold-related cro monomers, which are disordered in the crystals, and also, presumably, in solution, could also interact with the DNA (Figs 5, 6, 7). Such interactions could include Lys 62 and Lys 63. Presumably these C-terminal arms, which extend in solution like 'feelers', occupy well defined positions when complexed with the DNA. The finer details of the interactions between the cro repressor and its specific operator sequences are now being explored by more careful model building, and will be described elsewhere.

The proposed binding of cro to DNA explains many of the known properties of the complex. A tetramer or a dimer of cro bound to DNA extends over exactly 17 base pairs, the length of one operator (Figs 3, 5). The mode of interaction between protein and DNA is consistent with the approximate 2-fold symmetry of the operator sequence, and the symmetry of the protein. Also, the proposed binding explains, within the present level of detail, the chemical protection experiments (Figs 3, 6). Furthermore, there is a space of ~20 Å between cro molecules bound to adjacent operators, consistent with non-cooperativity of binding.²⁸

Fig. 5 Presumed interaction of cro repressor with DNA. Two monomers of cro (O and B), related by 2-fold symmetry axis Q, interact with the DNA so that axis Q coincides with the 2-fold symmetry axis of the DNA. The DNA has been rotated 90° relative to that in Fig. 3 so that its 2-fold symmetry axis is in the plane of the paper. The respective amino termini of the two cro molecules are labelled N_O and N_B . A pair of 2-fold-related α -helices occupy successive major grooves of the DNA and, closer to the symmetry axis, two extended polypeptide strands run parallel to the backbone of the DNA.

Fig. 6 Stereo view of the presumed interaction between two molecules of cro repressor and DNA, viewed along their common 2-fold symmetry axis. The open circles along the DNA backbone indicate the positions of the phosphates, those phosphates whose ethylation hinders cro binding (Fig. 3) are drawn solid.

Conclusions

This is the first structure determination of a specific DNA repressor, and the results obtained here may be of general relevance for interactions between proteins and DNA.

A principal feature of the proposed binding of cro to DNA is the use of symmetry. The 2-fold symmetry axis of the repressor coincides with the 2-fold symmetry axis of the DNA operator. This type of interaction is expected to be of general significance for proteins which recognize symmetric, sequence-specific regions of the DNA. Departures from exact symmetry could be important in 'fine tuning' of the strength of the DNA-protein complex. Our results indicate that the symmetric sequences often used for specific DNA-protein interactions are a consequence of the oligomeric structure of the regulatory proteins rather than the source of a special type of DNA structure.

Also, the α -helical conformation of proteins may presumably be used in both specific and nonspecific DNA binding. Sung and Dixon²⁹ were the first to propose that the histone H4 N-terminus adopts a helical conformation when interacting with chromatin nucleic acid. A related model has been proposed for *lac* repressor³⁰. Also, Warrant and Kim³¹ have presented direct evidence showing that protamine changes to an α -helical conformation on binding to a double-helical portion of crystalline tRNA. The cro repressor structure supports the notion that the binding of α -helices in the major groove of DNA may be a principal determinant in nonspecific protein binding to DNA, and is also of importance in specific recognition.

The structure of cro, and its complementarity to the B-form of DNA, suggest that the DNA retains the right-handed B-conformation when the repressor is bound. Of course, slight deformations of the DNA or protein could well occur on binding, and may be suggested by detailed model-building experiments, but the present results indicate that large adjustments in the DNA structure are not required to accommodate the protein. In contrast, McKay and Steitz³² have recently proposed that the cyclic AMP receptor protein of *Escherichia coli*, which promotes the action of RNA polymerase, binds to left-handed DNA. In the case of the cro repressor, the protein is located

Fig. 7 Stereo view of the presumed binding of a tetramer of cro to DNA. Monomers O and B, seen interacting with the DNA, are drawn with solid bonds, whereas monomers A and C which form a second potential DNA binding region on the opposite side of the tetramer, are drawn with open bonds. The broken line follows the 'bottom' of the major groove of the DNA. The DNA and protein have been rotated 30° about the horizontal axis so that the direction of view is essentially along the major groove of the DNA.

against one side of the DNA, with most of the specific recognition occurring between side chains of the protein and the parts of the bases that are exposed in the major groove of the DNA. There is no apparent need to expose the bases further to facilitate recognition.

We thank Drs Howard Schachman and Harrison Echols for their help in instigating this project. We also thank our

colleagues, in particular D. Bacon, R. G. Fisher, I. Herskowitz, M. F. Schmid, G. R. Smith, L. F. Ten Eyck and L. H. Weaver, for assistance and advice. This work was supported in part by grants from the NSF (PCM-8014311), the NIH (GM 20066, GM 28138), the MRC of Canada and the M. J. Murdock Charitable Trust. D. H. O. was supported by a Damon Runyan-Walter Winchell Cancer Fund Postdoctoral Fellowship (DRG-303-F).

Solar quiescent prominences at 10.7 GHz

R. N. Bracewell

Electrical Engineering Department, Stanford University, Stanford, California 94305, USA

W. Graf

SRI International, Menlo Park, California 94025, USA

Filaments on the Sun, which are dark linear features in the light of the Fraunhofer H α line, are a mysterious feature of the solar surface. They are blade-like extensions of the chromosphere projecting to a height of 40,000 km into the corona, and may extend for up to 200,000 km along the surface. The fact that they may persist for a year or so, disappear abruptly and then reappear in the same positions shows that they are superficial indicators of deeper phenomena. There have been several reports¹⁻⁴ of reduced brightness in the radio spectrum associated with the H α filaments, leading to the widely accepted view that filaments are associated with broad dark radio features. This picture is, however, contradicted by our observations at 10.7 GHz of one solar filament during the solar eclipse of 12 October 1977.

Although the filaments are very thin, subtending about 8 geocentric arc s when seen vertically, nevertheless, "regions of reduced radio brightness situated above filaments" were detected¹ in 1959 and explained in terms of "relatively cold prominences which are optically thick to 8-mm radiation". Later attempts to discern filaments at radio wavelengths succeeded due to use of the 11 m mm-wave telescope at Kitt Peak and the 42 m telescope at Green Bank²⁻⁴. In all cases temperature depressions in the neighbourhood of filaments were reported. Khangil'din's¹ interpretation was absorption in the filamentary material, Drago and Felli⁴ suggested that the temperature defect arose from lack of coronal emission from the volume occupied by the filament. The width of the depression was confirmed at ~2 arc min by Straka *et al*⁵ who proposed a model where the filament would exhibit a greater brightness temperature because the enhanced density within the filament would raise the height of the emission region. The general depression previously reported would then be due to the low-density 'cavity' surrounding the filament. Observations⁶ with the 100-m telescope at Effelsberg again confirmed the temperature depression. The depression was explained in terms of 'radio filament' for the 'temperature depressions' or 'absorption features' even though the width was perhaps five times larger than that of the dark optical filament. This interpretation in terms of absorption disagreed with Straka *et al*'s model⁵ of the cavity concept because Kundu *et al*⁶ believed that the cavity model

Fig. 2 Grooved terrain on Mars and Earth. Cross ridges in centre of images apparently dammed and ponded carving material, which eventually breached and deeply scoured the terrain at right. measured widths of as much as 180 km across the grooved terrain of Laurentide ice sheets in the Northwest Territories of Canada. The comparable width of grooved terrain in Kasei Vallis and Canada suggests that some of the ice on Mars may have been in sheets rather than valley glaciers.

Scarp heights of the martian channels also compare favourably with terrestrial glacial scarps. Scarps flanking Kasei Vallis lie near 2,000 m, and those at the mouth of Tiu and Ares Valles near 600 m. Grooves on the level ground above and below some of the scarps indicate that the ice may locally have inundated the scarps and may have been thicker than 2,000 m. Such heights are not excessive for terrestrial glacial terrain; scarp heights on Lambert Glacier in Antarctica are as much as 3,000 m, and the glacier presently is thicker than 2,000 m (ref. 11). Ice streams into the Ronne Shelf near the Ellsworth Mountains are 1,000–2,000 m thick¹² (Fig. 3). Pleistocene ice streams in Iceland are deduced to have been 1,000 m thick (based on the height of tablemountains)¹³, and the present-day Antarctic and the former Laurentide shields are 3,000–4,000 m thick¹⁴.

To determine whether ice sheets would have moved in martian conditions, it is important to obtain information on ice-surface gradients. Because no ice sheets are presently in the areas of interest, only the gradients of the martian channel beds can be obtained. For this discussion, however, ice-surface gradients can be assumed to be parallel. Regional gradients are very low and range from $<0.1^\circ$ to 0.25° ; local segments are steeper. Low ground gradients are no deterrent to glacial movement on Earth, however. For instance, the Yenta River in Alaska has a gradient of 0.06° , and the Wilkes subglacial basin in Antarctica has a gradient of $\sim 0^\circ$ for nearly 2,000 km. Thus, ground gradients apparently are not a critical determinant for glacial motion; indeed, glaciers are known to move uphill under certain circumstances. Terrestrial ice-sheet surface gradients range from 0.10° to 0.25° , from the Antarctic highs to outlet

glaciers on the coast, and thus are comparable to the gradients of martian channel beds.

It remains to be considered whether or not ice could have moved through martian outflow channels, given present and past martian environmental conditions. Sharp¹⁵ argued against the likelihood of glacial motion on Mars; however, he only considered the cold polar areas and not the warmer equatorial belt, where most outflow channels occur. Existing data on ice-deformation processes have been collected and displayed by Shoji and Higashi¹⁶ in a plot of shear stress versus temperature. Taking nominal values of surface slope (0.1 – 0.25°) and ice thickness (1,500–3,000 m), basal shear stresses (τ) may be calculated from the relation

$$\tau = \rho g y \sin \alpha \quad (1)$$

where ρ , g , and y are the ice density, gravitational acceleration, and depth, respectively, and α is the surface slope. When these shear stresses are plotted against martian equatorial temperatures (0° to -60°C), the conventional terrestrial processes characteristic of ice-sheet deformation—namely, dislocation creep and lattice-diffusion creep—also seem to apply to ice deformation on Mars. In addition, the shear stress–temperature field that is defined for Mars includes all the measured shear stress–temperature data obtained at various depths in drill holes at Byrd Station, Antarctica, and Camp Century, Greenland. These results strikingly illustrate the similarity in conditions on the two planets, notwithstanding the generally lower temperatures now prevailing on Mars.

Nominal strain rates, given in the plot of shear stress versus temperature by Shoji and Higashi¹⁶, vary by many orders of magnitude and diminish with decreasing temperatures and shear stress. These data suggest that ice, in present-day martian conditions, would have moved only very slowly. Several other factors, however, could increase the strain rate. Preferred crystal

Fig. 3 Streamlined island on Mars and Earth. Flow diverging around obstacles formed by islands on Mars and ice rises on Earth. Martian islands tend to be smaller than ice rises. Flow is towards the bottom. *a*, Kasei Vallis. North is towards the right. (Viking 519A29). *b*, Ice rises in Ronne ice shelf, Antarctica. Ellsworth Mountains on left. Radio echo sounding suggests subglacial breaching of ice rises by fjordlike troughs, which would further enhance their similarity to martian islands, north is towards the top right. orientation and occluded gas bubbles in polycrystalline ice sheets act to increase strain rates at given temperatures and shear stresses by as much as 100-fold^{17,18}. Strain rates can also be increased once flow by dislocation creep is initiated by local steeper slopes and the ice mass undergoes frictional heating. The energy thus released internally by an ice sheet flowing at a velocity of 20 m yr^{-1} is roughly equal to the normal geothermal flux. An ice velocity of 20 m yr^{-1} is not extraordinary and, on

Earth or Mars, could be considerably larger if ice-surface slopes increased to several degrees. Artesian water under the ice could also have contributed to lubrication of the bases of martian ice masses and thus accelerated their motion and increased their erosive power. The pronounced grooving on the channel floors indeed suggests that the ice moved over the ground and eroded powerfully. A warmer climate in the past, of course, would have favoured faster glacial motion.

Fig. 4 Dimensions of streamlined islands. Plotted scabland flood islands (■) and martian islands are from ref. 7; ×, Maja Vallis; ○, Kasei Vallis. Plotting of Antarctic ice-rise dimensions (●) on same trendline as scabland and Mars values indicates that sculpturing by ice is as likely as catastrophic flooding for causing streamlining.

Ice may have accumulated in the source area of the martian channels from atmospheric precipitation, wind-drifted frost and dust deposits, and from the ground as springs. All these processes no doubt contributed, but springs must have been dominant because the chaotic terrain, the source area of the channels, is highly disturbed, apparently owing to the removal of large quantities of material. The groundwater may have been under artesian pressure as proposed by Carr¹⁹, and created ice domes that then flowed to adjacent depressions to carve the channels. Alternatively, the water could have formed ice covers over incipient rivers that required only normal discharges²⁰. The river ice may have consolidated into ice drives⁷ and, eventually, ice streams. The internal deformation and flow of such ice streams may then have imparted to the martian channels their distinctive and spectacular morphology.

We thank H. Masursky, M. Grolier and V. Baker for helpful reviews (although their point of view is not necessarily that of the authors). This work was supported by NASA contract W14,575 and grant 150-6330A.

Decade fluctuations in geomagnetic westward drift and Earth rotation

Jean-Louis Le Mouél*, Theodore R. Madden†, Joël Ducruix* & Vincent Courtillot‡*

* Institut de Physique du Globe, Université Paris VI, 75230 Paris Cedex 05, France

‡ UER des Sciences Physiques de la Terre, Université Paris VII 75230 Paris Cedex 05, France

Numerous studies of the variations of the Earth's rotation have been made since 1900 (summarized in refs 1, 2). It seems well established that variations in the rotation with periods equal to or less than 2 yr are due to variations in the zonal circulation of the atmosphere^{2–4}. However, there is no general agreement about the cause of the longer-period variations of the Earth's rotation, sometimes known as the 'decade variations', although the most favoured explanation is electromagnetic core–mantle coupling (see ref. 5). Several studies^{6–8} of the correlation between Earth rotation and magnetic field variations have obtained marginally positive results. We have been able to clarify such a correlation over the past 120 yr by studying those magnetic field indicators that are the most sensitive to variations in westward drift of the outer regions of the core. We suggest here that the correlation can be extended back ~300 yr. Simple models of core–mantle coupling, based on Bullard's ideas, give reasonable quantitative agreement with the observations.

In 1951, Stoiko⁹ compared the variations of the Earth's magnetic field intensity observed at Paris with the variations of

Fig. 1 Plot of the secular variation of declination $\dot{D}$ (solid curve and right hand scale) and of the excess length of day $d(AT)/dt$ (dashed curve and left-hand scale) for the period 1861–1978. ΔT data are from refs. 18, 19. The relative changes in the Earth rotation rate $\Delta\Omega/\Omega$ are obtained from the $d(AT)/dt$ values through multiplication by -1.157×10^{-8} .

the length of day for the period 1883–1948 and claimed a good correlation between the two. In 1953 Vestine⁶ proposed a correlation between the westward drift of the eccentric dipole (the magnetic centre C) and the variations of the Earth's rotation rate Ω for the period 1885–1945, and gave a qualitative interpretation of this result using Bullard's model. Vestine and Kahle¹⁰ extended the correlation up to 1965. A puzzling feature of this correlation is that the magnetic variations seem to lag behind the Ω variations. The variations of the longitude of C for the period 1945–75 have been found¹¹ to have a poor correlation with Ω . More recently, it has been shown^{12,13} that, starting in 1969, there was a rapid acceleration of the secular variation of the east (Y) component of the magnetic field across large regions of the Northern Hemisphere and that a similar event occurred around 1900 (although it is more difficult to ascertain its global nature because of the lack of magnetic observatories at that time). Minima in Ω were also noted at about the same times. It is this correlation between the Y variations and Ω which we consider and extend here.

Motions of the top layers of the core are responsible for most magnetic variations seen at the Earth's surface on the decade time scale; the westward drift of magnetic features which has long been noted^{14,15} can be taken as evidence for a westward drift of the upper core. Hide¹⁶ has pointed out that such motions could be the result of slow MHD–Rossby waves, but the simultaneity of the changes in these motions seen around the world makes this possibility unlikely.

To study the westward drift of magnetic features we have to distinguish between the drift effect and other causes of magnetic variations¹⁷. The magnetic secular variation can be written as:

$$\frac{\delta B}{\delta t} = \frac{\partial B}{\partial t} + U_{\phi} \frac{\partial B}{\partial \phi}$$

where $\delta B/\delta t$ is the magnetic variation seen at magnetic observatories; the $\partial B/\partial t$ term accounts for the effects of non uniform and north–south motions (as well as the less important effects of magnetic diffusion), U_{ϕ} is the magnitude of the westward drift as seen at the Earth's surface and $\partial B/\partial \phi$ is the longitudinal gradient of the magnetic field as seen at the surface.

Declination D (or the closely associated east component Y) is especially suited to studies of zonal motions because (1) it has weak gradients in the north–south directions compared with the other components and (2) it was more accurately and frequently determined in earlier times.

To study the detailed time history of the magnetic secular variations data from continuously recording magnetic observatories are needed. Most of the early magnetic observatories are located in Europe and it is fortunate that here the $\partial Y/\partial \phi$ term is large and smoothly varying. Thus $\delta Y/\delta t$ is dominated, at

Fig. 2 Selected $\delta Y/\delta t$ variations (in nT yr^{-1}) around the period of apparent westward drift minimum of 1969.

least for the past century, by the term $U_\phi(\partial Y/\partial \phi)$, and $\dot{Y}$ (or $\dot{D}$) should be proportional to U_ϕ . For Paris $\partial Y/\partial \phi$ is $\sim 150 \text{ nT per deg}$ and $\partial D/\partial \phi$ is $\sim 0.4\text{--}0.5$. If core-mantle coupling is the cause of the decade variations in Earth rotation one should expect a good correlation between $\dot{Y}$ (or $\dot{D}$) as seen in Europe and Ω .

Figure 1 displays $\dot{D}$ and $\Delta\Omega/\Omega$ for the period 1861–1978. The D values are from a compilation of available data from the Paris area. These data can be considered as representative of the western European area, as has been shown for the recent observatory data¹³. $\dot{D}$ has been averaged over 5 yr. The Ω data for 1861–1978 are from refs 18, 19.

The data of Fig. 1 show a good correlation between $\dot{D}$ and Ω , significantly better than in any previous study (see Fig. 4 of ref. 10 or Fig. 4 of ref. 8). The magnetic variations lead, rather than lag⁷, the Ω variations by $\sim 10 \text{ yr}$. (The coherency peaks fairly sharply at about 0.8 for this value of the lag. A more sophisticated correlation analysis is not warranted for the kind of data shown in Fig. 1 and the eye is still the best judge.) These variations are quite pronounced. From $\dot{D}$ one can infer that the westward drift decreased from ~ 0.3 to 0.1 deg yr^{-1} between 1870 and 1900, increased again from ~ 0.1 to 0.4 deg yr^{-1} between 1900 and 1925 and decreased again to $\sim 0.1 \text{ deg yr}^{-1}$ in 1969 (see also ref. 11). Since then a rapid acceleration of the drift has been seen, which is quite similar to that observed just after 1900.

The most pronounced features of secular variation are the discontinuities in the slope of $\dot{Y}$ seen in 1900 and 1969, and somewhat less clearly in 1925, which we interpret as sudden changes in the acceleration of the westward drift, $\dot{U}_\phi$. The number and distribution of magnetic observatories in 1900 were too limited to ascertain the global character of the drift acceleration changes, but by 1969 the situation was greatly improved. Fig. 2 shows selected results from a preliminary study, still in progress, which shows that in most areas where we expect to see the effects of rapid changes in the slope of U_ϕ they are indeed observed. The examples in Fig. 2 come both from regions where $\partial Y/\partial \phi$ is large and smoothly varying (for example, Europe^{12,13}) and from regions where $\partial Y/\partial \phi$ is close to zero (for example, Honolulu): in the former a clear extremum of

$\partial Y/\partial \phi$ is observed, in the latter there is none. However, in some cases (for example, South America) discrepancies are found which may be due to the evolution of more localized magnetic features. In any case, the magnetic data are not incompatible with a global zonal circulation pattern existing in the upper core which underwent a rapid change of acceleration in 1969^{13,20}.

We can only attempt here to identify some of the parameters that are relevant in a quantitative study of core-mantle coupling and estimate their magnitudes. We follow Bullard's model of a convecting core which causes differential rotation between the outer regions and the inner regions. This differential rotation creates a toroidal magnetic field in the core which penetrates into the lower mantle¹⁵. Thus, the mantle, upper and inner core are all electromagnetically coupled, and, if the convection regime changes, the core and mantle will all undergo changes in their angular velocities, the net angular momentum remaining constant. When the upper core region is thin, the mantle follows the inner core and will accelerate when the upper core decelerates (see ref. 20, with lower mantle conductivity estimates from ref. 21): this is what is observed. The thickness of the upper core zone can be estimated by assuming that the mantle and lower core are rotating together. Using the law of conservation of momentum and the observed proportionality rate between $\delta\Omega$ and δU_ϕ (with $\delta\Omega \sim 3 \times 10^{-12} \text{ rad s}^{-1}$ and $\delta U_\phi \sim 0.2 \text{ deg yr}^{-1}$) a thickness of 100 km is found for this upper region. The time lag of the changes in Ω relative to U_ϕ is a measure of the magnitude of the coupling between the mantle and the inner core, which in turn depends on the magnitude of the toroidal field in the core and the conductivity of the lower mantle. The observed time lag can be accounted for by the above model (Le Mouél and Courtillot, in preparation).

We have also compared data for the period 1700–1870. Despite low reliability, these older data do not display the dramatic changes that have occurred since 1870. These observations seem to imply that the period 1700–1870 was a more stable regime for core motions than the following century. The similarity of the magnetic situation in 1900 and 1969 leads us to predict that the Earth rotation is presently at the beginning of a period of acceleration.

Phonon scattering at grain boundaries in heavily doped fine-grained silicon-germanium alloys

D. M. Rowe, V. S. Shukla & N. Savvides*

Department of Physics, Electronics and Electrical Engineering, UWIST, Cardiff CF1 3NU, UK

Thermocouples made from heavily doped n- and p-type silicon-germanium alloys are used in the nuclear powered thermoelectric generators which provides onboard power to the American Voyager spacecraft. The isotopic heat source is expensive and any improvement in the generators' heat energy to electrical energy conversion efficiency would save both money and weight. The possibility of reducing the thermal conductivity of thermoelectric semiconductor alloys by compacting fine grained material has been considered and various estimates have been made of the reduction in thermal conductivity with grain size. The electrical properties of hot pressed compacts of heavily doped silicon germanium alloys which possess density values close to that of single crystal are unaffected by grain boundary scattering effects. Consequently, this method of preparation holds out a possibility of improving the 'figure of merit' of the thermocouple material and hence the conversion efficiency of the generator. Here the first measurements of the thermal diffusivity of fine grained hot pressed compacts of heavily doped n-type silicon germanium alloy are reported. The compacts investigated possessed grain sizes (L) in the range $10 < L < 25 \mu\text{m}$, $5 < L < 10 \mu\text{m}$ and $< 5 \mu\text{m}$. The results confirm that the lattice thermal conductivity decreases with a reduction in grain size. In the compact with $L < 5 \mu\text{m}$, this reduction is $\sim 28\%$ compared with 'single crystal' material. Within experimental error ($< 5\%$) the Seebeck coefficient and electrical resistivity do not change with grain size. This implies that the conversion efficiency of a thermoelectric generator employing silicon-germanium thermocouples would be significantly improved through the use of fine-grained thermocouple material.

The conversion efficiency of a semiconductor thermocouple depends on the temperature difference over which the device operates, its average temperature and the so-called figure of merit Z for the thermocouple material. $Z = S^2\sigma/K$ where K is the thermal conductivity, S the Seebeck coefficient and σ the

Fig. 1 Microphotograph of a typical polished surface of a compact after etching with CP4. Grain size is in the range $10 < L < 25 \mu\text{m}$. Scale bar, $14 \mu\text{m}$.

electrical conductivity. The thermal conductivity is the sum of the contribution arising from the lattice waves (phonons) K_L and a contribution K_e from the carriers present. All three parameters in the figure of merit vary with the carrier concentration and Z is optimized at around 10^{26}m^{-3} . At this high carrier concentration K_L still accounts for more than 75% of the thermal conductivity².

Interest has grown recently in the use of hot pressing techniques. Apart from facilitating device fabrication, the method of preparation has held out a possibility of reducing the lattice thermal conductivity and hence improving the figure of merit without adversely affecting the other thermoelectric parameters—an effect attributed to phonon scattering at the grain boundaries³.

The role of boundary scattering in limiting the phonon mean free path has long been considered as a low temperature phenomenon, where in the absence of other phonon scattering mechanisms boundary scattering effects are observed as the phonon mean free path approaches the sample dimensions. In solid solutions such as silicon-germanium alloys, however, because a large proportion of the heat is carried by low frequency phonons, boundary scattering effects can manifest themselves in the region of the Debye temperature and above and in principle lead to a reduction in the lattice thermal conductivity.

In thin films of germanium the carrier mean free path is unaffected by boundary scattering down to thicknesses of $0.1 \mu\text{m}$ (ref. 4) and measurements on high density heavily doped hot pressed silicon germanium alloys with grain sized $< 70 \mu\text{m}$ (ref. 5) and $< 10 \mu\text{m}$ (D.M.R. and N. Madini, unpublished data) indicate that the electrical conductivity and Seebeck coefficient differ from single crystal values by less than 5%.

In 1976 a theoretical model was proposed for heavily doped fine grained silicon germanium alloys⁶ but the combination of hot pressing and heavy doping complicates the situation, and in spite of refinements to the model there had been no satisfactory quantitative description of the thermal and electronic behaviour⁷. However, some theoreticians agree that in alloys with a grain size of $< 1 \mu\text{m}$ a reduction in K_L of 20–30% compared with the K_L for single crystal material would be observed.

Fig. 2 $K_{\text{hot pressed}}/K_{\text{single crystal}}$ as a function of grain size for heavily-doped silicon-germanium alloys.

We investigated material cut from a single ingot of homogeneous, zone levelled $\text{Si}_{63.5}\text{Ge}_{36.5}$ alloy doped n-type with phosphorus to about $1 \times 10^{26} \text{ m}^{-3}$. A disk shaped sample with suitable dimensions for thermal diffusivity measurement (6 mm diameter $\times$ 1 mm thick) was cut from a slice from the ingot using an ultrasonic cutter. The remainder of the slice was crushed in an agate pestle then ground in an agate vibromill. The fine powder was sieved through a set of British Standard microplate sieves assisted by ultrasonic vibration⁸. Compacts 10 mm in diameter and 3 mm thick were prepared from starting powders possessing a grain size in the range $10 < L < 25 \mu\text{m}$, $5 < L < 10 \mu\text{m}$ and $< 5 \mu\text{m}$ using a vacuum hot pressing technique⁹. The density of the compacts was better than 98% of that of the single crystal starting material. A typical microphotograph of the polished surface of a compact is shown in Fig. 1, and it is apparent that little, if any, grain growth has occurred during compaction. A disk shaped sample was cut from each of the compacts and all four disks annealed at $1,000^\circ\text{C}$ under vacuum for 1 h followed by quenching in cold water to normalize the carrier concentration and hence the value of K_e (ref. 10).

The thermal diffusivity α of the 'single crystal' starting material and of the three compacts was measured using a system based on the laser flash technique¹¹. Measurements on ARMCO iron indicated that the accuracy of the system was better than $\pm 2\%$ at room temperature. Reproducibility of measurements was about the same. Seebeck coefficient data were obtained using a hot probe method (accuracy $\pm 3\%$) and carrier concentration and electrical resistivity values derived from carrier concentration versus Seebeck coefficient¹² and electrical resistivity curves¹³.

The experimental results are displayed in Table 1. Thermal conductivity values were obtained from the measured thermal diffusivity using the relationship $K = C_p \alpha$ where C_p is the specific heat per unit volume at constant pressure and values appropriate to the alloy investigated are taken from the literature¹². The electronic contribution to the thermal conductivity is given by $K_e = \mathcal{L}(k/e)^2 \sigma T$. Where $\mathcal{L}$ depends on the scattering mechanisms of the charge carriers and for the material investigated is ~ 2.9 (ref. 7). The Seebeck coefficient of the three compacts are very similar but all are higher than the 'single crystal' starting material. This increase in Seebeck coefficient and the corresponding increase in electrical resistivity is due to a relatively small loss of dopant during the hot pressing operation. The lattice thermal conductivity decreases with a reduction in grain size and for the compact with a grain size $< 5 \mu\text{m}$ is about 28% less than the 'single crystal' starting material.

Our results are in reasonably good agreement with theory (Fig. 2) and confirm that in fine grained heavily doped silicon germanium alloys phonon scattering at grain boundaries results in a significant reduction in the lattice thermal conductivity. The implication is that thermoelectric generators which employ thermoelements fabricated from fine grained semiconductor alloys should exhibit substantial improvement in performance over those based on 'single crystal' or large grained materials.

We thank the British Gas Corporation for partial support of the project, Professor D. J. Harris for use of departmental facilities, and Dr R. D. Nasby for supplies of alloy.

Estimate of annual variation of Atlantic Ocean heat transport

Peter J. Lamb

Cooperative Institute for Marine and Atmospheric Studies,
The University of Miami/NOAA, Miami, Florida 33149, USA
and * Climatology Section, Illinois State Water Survey, Champaign,
Illinois 61820, USA

Despite the importance of meridional oceanic heat transport for the understanding of the climate system^{1,2}, most existing hemispheric and ocean basin estimates are necessarily indirect. Annual averages have been obtained for individual basins from sea-air heat exchange results³⁻⁷, and for each hemisphere from measurements of net radiation at the top of the atmosphere and calculations of atmospheric energy transport^{8,9}. The latter approach, when used in conjunction with atmospheric and oceanic energy storage information, has provided monthly mean estimates of the meridional heat transport by the total Northern Hemisphere water body, but not its separate oceans¹⁰. I now present an estimate of the annual variation of meridional heat transport in the Atlantic Ocean, based on large sets of sea-air interaction and subsurface temperature data, which suggests that, with the possible exception of November-December, the heat flux is northward.

Bimonthly averages of the 'vertically and zonally integrated net meridional heat transport' (VZINMHT) within the North and Tropical Atlantic Ocean (70°N - 20°S , including the Gulf of Mexico and Caribbean Sea) were obtained for fixed latitude circle arcs spanning the entire basin (Table 1). The fundamental equation used was that for the heat budget of a local oceanic column,

$$Q_v = Q_{\text{scf}} - Q_t \quad (1)$$

where Q_v is the rate of lateral heat import/export by oceanic motions, Q_{scf} is the rate of net surface heat gain, and Q_t is the column's heat storage change rate. We computed average bimonthly integrals of these terms, with dimensions of Watts, for 10° (extratropics) and 5° (tropics) latitude zones extending across the basin. Those for Q_{scf} were obtained from existing sea-air heat exchange results. The Q_t integrals were estimated using a set of subsurface temperature data acquired and processed for this purpose. These results permitted Q_v to be obtained from equation (1). The zonal Q_v integrals were then converted into VZINMHT estimates (dimensions of Watts) for the zones' bounding latitude circle arcs, by successively integrating southwards from assumed near-zero 70°N VZINMHT boundary conditions computed from ref. 11 (Table 1). The uncertainty in the VZINMHT results given by this procedure naturally increases away from 70°N , and becomes large in the tropics. This is shown in Table 1. Such uncertainty arises from the use of empirical equations to estimate Q_{scf} , and from possible temporal and spatial sampling biases and instrumental inaccuracies in the data sets described below.

Northward transports are positive; those for 70° N are boundary conditions computed from Aagaard and Greisman¹¹. Vertical integrations to 300 m and 500 m depths are given separately. The domain treated has the following noncontinental lateral boundaries: Baffin Island east coast, 64° W in Hudson Strait, 66° W in Gulf of St Lawrence, 6° W in Strait of Gibraltar, and 8° E in Skagerrak Strait. The bimonthly uncertainties (10^{13} W) are based on possible errors of 15 W m^{-2} in both Q_{sc} and Q_e (refs 6, 10) and 5×10^{13} W in the 70° N boundary transports. The annual average VZINMHTs listed are computed from annual average Q_{sc} s; they are very similar to the annual means of the bimonthly VZINMHTs cited, due to the annual average Q_e being extremely close to zero. The annual uncertainties (10^{13} W) are based on possible errors of 10 W m^{-2} in the annual average Q_{sc} and 5×10^{13} W in the 70° N boundary transport.

The bimonthly average zonal Q_e integrals were estimated from 233,957 individual temperature soundings, using a 5° square spatial resolution. January–February values were obtained from the difference between the mean heat storage for December–January and February–March, and those for other bimonthly periods were calculated similarly. The temperature soundings used were drawn from the 1967–76 files of a National Oceanographic Data Center (Washington DC) global set which has been fully described by Levitus and Oort¹². Their spatial density is greatest between 30° and 40° N, from which it decreases both northwards and southwards (Table 2). Because of uncertainty about the representativeness of the sub-250 m annual temperature variations¹⁰ (only 54% and 20% of the soundings reach 300 m and 500 m, respectively), Q_e was computed for both the upper 300 m and upper 500 m. Table 1 contains VZINMHT estimates derived from each set of Q_e results.

The bimonthly average zonal Q_{sc} integrals were calculated from the monthly mean sea–air heat exchange results of Bunker (70°–30° N) and Hastenrath and Lamb¹³ (30° N–20° S). Both these studies obtained long-term averages of Q_{sc} from the surface heat budget equation

$$Q_{\text{sc}} = \text{SW}\downarrow - \text{LW}\downarrow - Q_s - Q_e \quad (2)$$

The right-hand terms, which denote the net shortwave ($\text{SW}\downarrow$) and net longwave ($\text{LW}\downarrow$) radiation and the turbulent fluxes of sensible (Q_s) and latent (Q_e) heat, were estimated using conventional empirical equations and several million surface marine meteorological observations obtained from the National Climate Center (Asheville, NC). The data bases, methods, and uncertainties of each investigation have been fully discussed previously^{13–16}. Bunker's results, which are for Marsden (that is 10°) square subareas of varying size¹⁴, were derived from turbulent fluxes computed using the individual observations and variable drag coefficients necessary for the extratropics. Hastenrath and Lamb's results were preferred to Bunker's in the tropics because of the apparent superiority of their $\text{SW}\downarrow$ input¹⁶, and the fact that their 1° square spatial resolution permitted the use of 5° latitude zones in this energy source region for the climate system. Bunker's format required 10° zones.

The most important annual average VZINMHT result in Table 1 is that this flux is directed northwards throughout the study region. It increases from 81×10^{13} W at 20° S to a broad 5°–25° N maximum of 111 – 115×10^{13} W, due largely to substantial enhancement between 5° S and the Equator. There is a pronounced decrease poleward of 30° N, especially between 30° and 40° N. The general pattern of these results is very similar

to that recently obtained by Hastenrath⁶, whereas earlier work found the mean annual VZINMHT to have a northwards maximum near 30° N^{3,5}, weak northwards^{3,4}, or near zero⁵ cross equatorial values, and a southward direction throughout almost all of 0°–20° S (ref. 5). From 40° N southwards, however, Hastenrath's⁶ northwards VZINMHTs are 40–60% larger than the present ones. This difference primarily results from Hastenrath's 40°–50° N Q_{sc} (taken from Budyko¹⁷) being more negative than the Bunker value used here. Budyko¹⁷ failed to detect the warming of the Labrador current between Nova Scotia and Cape Hatteras Identified by Bunker and Worthington¹⁵. The present annual average VZINMHT for 25° N ($+113 \times 10^{13}$ W) is in good agreement with Bryden and Hall's¹⁸ recent direct computation from oceanographic measurements ($+110 \pm 29 \times 10^{13}$ W).

Many of the bimonthly VZINMHT estimates in Table 1 possess considerable uncertainty, which requires that they be treated with some caution. Their most important result is the suggestion that northward transports may prevail throughout almost all of the study region during January–October. The northward flux out of the Northern Tropics seems to be strongest during July–October, when (particularly in September–October) the northwards VZINMHT may also be largest at 20° S and the Equator. This pattern is strongly enhanced for September–October when the storage computations are extended to 500 m. The northwards VZINMHT evidently undergoes only a relatively small reduction in the Northern Tropics during July–October, whereas much more pronounced decreases are indicated for the 40°–50° N (July–August) and 30°–50° N (September–October) zones. May–June, in contrast, seems to be characterized by a northward VZINMHT that is very weak at 20° S and the Equator, increases strongly between 0° and 15° N, approaches that of July–August at 30° N, then decreases uniformly to 50° N.

The most significant March–April result is the pronounced increase in the northward VZINMHT suggested to occur between 5° S and the Equator (Table 1). This converts a moderate northward flux at 20° S into an equatorial one comparable with that of July–October, and seems primarily responsible for the marked 5° S–0° increase in the annual average VZINMHT (Table 1). During this bimonthly period, the 0°–5° S zone experiences both a moderate positive Q_{sc} and pronounced cooling in the upper 300 m (not shown). A progressive decrease of the March–April transport occurs north of 5° N. Table 1 suggests January–February is characterized by a northward VZINMHT that is quite small at 20° S, undergoes a moderate increase to 30° N, and may be stronger than other bimonthly periods at 50° and 60° N. The latter feature, along

Table 2 Number of 1967–76 subsurface temperature soundings available for 10° latitude zones of the Atlantic (including the Gulf of Mexico and Caribbean Sea), and the area of ocean surface (10^{12} m²) in each zone

Latitude zone	Ocean surface area	No. of soundings
60°–70° N	2.94	10,184
50°–60°	4.19	21,913
40°–50°	5.31	45,869
30°–40°	6.95	79,119
20°–30°	8.80	41,233
10°–20°	8.00	21,223
0°–10° N	6.64	6,763
0°–10° S	6.16	4,943
10°–20°	6.12	2,710

The noncontinental lateral boundaries of the domain treated are specified in Table 1.

with the VZINMHT relative minimum at 40° N, arise from the North Atlantic having a maximum negative Q_{stc} between 30° and 40° N at a time when its cooling is strongly concentrated in the 40°–50° N zone (not shown). However, the comparative lack of winter subsurface temperature data for this region (only 44% of summer amount between 40° and 60° N) may render the foregoing results suspect.

The remaining significant feature of Table 1 is that its November–December results are in marked contrast to those for the rest of the year. The VZINMHT is suggested to be directed southwards throughout much or even all of the study region during November–December, and to show a general increase in this direction to a maximum at 10°–20° S. This is particularly indicated by the estimates derived from 500 m Q_i integrals, which have substantial magnitude south of 40° N. Much weaker, and extremely uncertain, southward VZINMHTs were yielded by the 300 m Q_i calculations, especially north of the Equator (Table 1). These November–December results arise from the oceanic cooling, especially when estimated to 500 m, exceeding the negative Q_{stc} north of 10° N (except for 30°–40° N), and from positive Q_{stc} values coinciding with lesser oceanic warming or oceanic cooling south of 10° N (not shown).

Although the November–December results are rather surprising and therefore of potential interest, they should be regarded as highly tentative. In particular, there does not seem to be a fully acceptable rationale for the southward VZINMHT currently available. Furthermore, the higher latitude Q_i and Q_{stc} estimates, on which all VZINMHTs depend, have a poorer data base for the cooler months than the rest of the year. Some relevant statistics were given above. If the November–December VZINMHT is in reality directed northwards rather than southwards, however, the present results probably imply that such northward transport is weaker than in the other bimonthly periods. The November–December results in Table 1 may therefore serve as a challenge to theoreticians and further stimulus for the planned programme to monitor the Atlantic VZINMHT near 25° N (refs 19, 20) directly.

I thank Eric B. Kraus for enabling me to undertake this research, and Stanley A. Changnon Jr for assistance. It was supported by NSF grant ATM 77 28126 to CIMAS, the State of Illinois, and the University of Adelaide Study Leave Programme. The late Andrew Bunker supplied sea–air heat exchange results, and Henry Poor gave computer support. I thank E. Kraus, C. Rooth, J. Merle, S. Hastenrath and W. Wendland for helpful comments.

Dissolved state of chromium in seawater

Eiichiro Nakayama, Hiroyuki Tokoro,
Tooru Kuwamoto & Taitiro Fujinaga

Department of Chemistry, Faculty of Science, Kyoto University,
Kyoto 606, Japan

The dissolved state of chromium in seawater has long been studied and in particular which species, trivalent or hexavalent, is predominant. Research results are not, however, consistent, although the method used has usually been the same—using ferric hydroxide as coprecipitation carrier (Table 1^{1–7}). We have studied the coprecipitation behaviour of chromium with ferric hydroxide and other metal hydroxides in the presence of naturally existing inorganic and organic ions to attain an accurate analytical method for determining chromium content, as well as to estimate its behaviour in natural waters^{8,9}. We report here that neither Cr(VI) nor organic species coprecipitate with ferric hydroxide in seawater; Cr(VI) can be quantitatively captured by the coprecipitation with bismuth hydroxide without any pretreatment (such as reduction); and the role of manganese oxide should be considered in addition to the amount of dissolved oxygen to understand the redox system of chromium in natural waters. The inconsistency of the past research may therefore be partly because the presence of organic species was not taken into account and was analysed as either Cr(VI) or Cr(III) or overlooked entirely.

We have developed a method for the fractional quantitative determination of chromium in seawater. A 1.2-l sample of seawater was filtered through a 0.4- μ m nucleopore filter immediately after which the sample was divided into three. To the first and second portions were added respectively ferric hydroxide and bismuth hydroxide precipitates, which had been prepared separately and thoroughly washed with distilled water. In seawater solution with a pH ~8 inorganic Cr(III) only coprecipitates quantitatively with ferric hydroxide, inorganic Cr(III) and Cr(VI) coprecipitate with bismuth hydroxide while the organic species hardly precipitate at all with either hydroxide. The third portion was acidified with hydrochloric acid and heated with ammonium persulphate to decompose any organic matter. The pH of this portion was then adjusted back to 8 with aqueous ammonia and bismuth hydroxide was added. After these portions had been allowed to stand for 12 h, the precipitates were filtered and dissolved in hydrochloric acid. The iron and bismuth was removed by the solvent extraction method using a *p*-xylene solution of 5% tri-isooctylamine, the aqueous phase evaporated to dryness, and the residue dissolved in a small amount of diluted nitric acid. The resulting solution was used for flameless atomic absorption analysis. The total amount of inorganic Cr(III) present was determined from the first portion; the total inorganic Cr(III) and Cr(VI) from the second portion; and the total amount of chromium, including the organic species from the third portion. By performing the experiment with a ⁵¹Cr tracer, it was found that the recovery of chromium was >95% in the coprecipitation procedure and >99% in the other procedures. The procedure was repeated five times with each

Fig. 1 Vertical distribution of chromium species and some standard components in the Pacific Ocean ($32^{\circ} 19.3' \text{ N}$, $137^{\circ} 33.5' \text{ E}$; depth 4,079 m). a, Particulate chromium; b, dissolved inorganic Cr(III); c, dissolved Cr(VI); d, organic chromium species; e, dissolved oxygen; f, pH; g, salinity.

sample and the standard deviations for the first, second and the third portions were 5.8, 2.4 and 5.1% respectively. The amount of particulate chromium present was determined by analysing the filter paper used for filtrating the sample.

Although there was no particular quality control to minimize chromium contamination, seawater sampling was usually carried out in the direction of the wind and plastic Niskin-type bottles were used to avoid metal contamination in our research vessel.

This method was used to analyse the samples of seawater collected in the adjacent seas of Japan in the summer of 1979. Figures 1 and 2 show typical results from six stations in the Pacific Ocean and four stations in the Japan Sea, respectively. The total average concentration of dissolved chromium is $9.4 \times 10^{-9} \text{ M}$ ($0.48 \mu\text{g l}^{-1}$) in the Pacific Ocean and $8.1 \times 10^{-9} \text{ M}$ ($0.42 \mu\text{g l}^{-1}$) in the Japan Sea: consisting of 10–20% of inorganic Cr(III), 25–40% of Cr(VI) and 45–65% of organic species. The average concentration of particulate chromium is

Fig. 2 Vertical distribution of chromium species and some standard components in the Japan Sea ($44^{\circ} 11.9' \text{ N}$, $138^{\circ} 56.4' \text{ E}$; depth 3,447 m). a, Particulate chromium; b, dissolved inorganic Cr(III); c, dissolved Cr(VI); d, organic chromium species; e, dissolved oxygen; f, pH; g, salinity.

Table 1 Literature data on the chromium contents in seawater

Ref.	Locations	Concentration of chromium ($\mu\text{g l}^{-1}$)	Ratio of Cr(VI)/Cr(III)
1	British coastal	Cr(III) 0.46 Cr(VI) 0	Cr(III) only
2, 3	Ligurian Sea	Cr(III) 0.02–0.25 Cr(VI) 0.05–0.36	Cr(VI) > Cr(III)
4	Pacific Ocean	Cr(III) 0.13–0.90 Cr(VI) 0.07–0.27	Cr(VI) < Cr(III)
5	Equatorial region of Pacific Ocean	Cr(III) 0.24–0.52 Cr(VI) 0.03–0.11	Cr(VI) < Cr(III)
6	Northern north Pacific Ocean	Total Cr 0.16–0.95 Cr(VI) 5–70%	Cr(VI) < Cr(III)
7	North-east region of Pacific Ocean	Cr(III) 0.005 Cr(VI) 0.15	Cr(VI) > Cr(III)

$3.6 \times 10^{-10} \text{ M}$ ($0.07 \mu\text{g l}^{-1}$) in the Pacific Ocean and $4.2 \times 10^{-10} \text{ M}$ ($0.08 \mu\text{g l}^{-1}$) in the Japan Sea. Figures 1 and 2 show that the vertical distribution of Cr(VI) differs between the two Seas. In the Pacific Ocean there is a remarkable increase at a depth of 1,000 m and below while in the Japan Sea there is a decrease. The ratio of Cr(VI) to inorganic Cr(III) averages 2.7 in the Pacific Ocean while in the Japan Sea it averages 1.8. This difference cannot be explained by thermodynamical equilibrium and application of the oceanographical data, such as pH and dissolved oxygen¹⁰, because the two seas are completely oxygenated. Hence we propose a model for the circulation of chromium in seawater as shown in Fig. 3. This model was supported by an experiment based on the geochemical fact that in manganese nodules the chromium content is extremely low compared with that in the marine sediments composed of clay minerals¹¹. Thus, when the seawater solution containing 10^{-5} M of Cr(III) was bubbled with air for >300 h no hexavalent chromium was detected. However, when about 50 mg l^{-1} of powdered manganese oxide (such as synthesized manganite and manganese nodules) were added, 10% of Cr(III) was oxidized within 100 h. Organic complexes of Cr(III) (such as chromic citrate) were not oxidized within 100 h even if excess manganese oxide was present. From this model, the behaviour of chromium in seawater can be explained as follows. When inorganic Cr(III) is adsorbed by suspended particles it is oxidized by the catalytic action of manganese oxide during sedimentation or in the marine sediments. Direct oxidation with dissolved oxygen only is not appreciable. Cr(VI) is reduced by being taken into organisms or by reductive organic matter. When organic species form, oxidation ceases.

Thus we interpret the difference of distribution of Cr(VI) between the two Seas as being due to the fact that the marine sediments contain abundant manganese oxide in the Pacific Ocean because they are oxygenated down to a considerable depth, whereas the sediments in the Japan Sea, except for a thin oxygenated layer at the surface reduce manganese oxide to Mn(II) (ref. 12). Accordingly, Cr(VI) is supplied to the water

**Fig. 3** A model for the circulation of chromium in seawater.

column in the Pacific Ocean, but not to the Japan Sea. In addition, the Cr(VI) supplied from suspended particles does not seriously effect its vertical distribution because their chromium content is very low.

We thank members of the staff of the Ocean Research Institute, University of Tokyo for their cooperation in the collection of samples.

Effect of irregular fluctuations in Antarctic precipitation on global sea level

J. Oerlemans

Institute of Meteorology and Oceanography, University of Utrecht, Postbus 80.005, 3508 TA Utrecht, The Netherlands

One of the reasons for the continuing interest in the global sea level is that secular variations may be caused by climatic changes. Such a change could, for example, be an atmospheric warming due to CO_2 accumulation. Changes in the amount of ice in the major ice sheets will be reflected in secular variations of sea level; it has, for example, been suggested that ice-shelf thinning may change the drainage of parts of the Antarctic Ice Sheet¹. Attempts to monitor climatic change by measuring global sea level will, however, be complicated by random fluctuations of the ice volume in the major ice sheets, themselves the consequence of random variations in the ice accumulation rate. Precipitation rates are highly variable, and this also applies to Antarctica², which stores most of the continental ice mass. By means of a simple model for ice flow in the Antarctic, together with proxy data on precipitation variability derived from ice cores, I show that long-term sea-level variations with a standard deviation of roughly 5 cm are to be expected on this account. This 'climatic noise' is comparable in magnitude with many of the secular effects now being sought.

Any changes in the volume of the Antarctic Ice sheet are damped by a mechanism involving several drainage systems³. In these systems ice is discharged to the ocean by horizontal pressure gradients resulting from differences in elevation of the ice surface. If the ice thickness of a drainage system is increased (without changing the mass balance—the yearly gain of ice mass at the surface), the mean pressure gradient from the interior of the drainage system to the ocean will become larger. The subsequent increase in ice-mass discharge will try to restore the original ice thickness. In the following, we will measure the strength of this damping by the relaxation time, t_R , which indicates how fast the system can return to equilibrium.

Once this time scale is known, the effect of random fluctuations in the mass balance on the volume of the Antarctic Ice Sheet can be estimated with a simple stochastic model. A framework for the application of stochastic models to climate problems has been presented by Hasselmann⁴. Here I will use a simple model, consisting of a rate equation for ice thickness with a linear damping term and an additive stochastic term to represent the fluctuations in the ice accumulation rate.

Fig. 1 Steady-state ice thickness H_0 , as a function of the mass balance G_0 , for three values of the flow parameter K ($\text{m}^{-3/2} \text{yr}^{-1}$). The vertical line indicates the present mass balance over Antarctica.

To obtain a value for t_R , we can turn to a schematic physical description of the dynamics of large ice streams. As proposed by Nye⁵, we use a flow law for the vertically integrated horizontal ice velocity (denoted by u), which should account for both internal deformation and (moderate) basal sliding. It reads

$$u = k\tau_b^m \quad (1)$$

where τ_b is the basal shear stress and k and m are constants. The basal shear stress is proportional to the ice thickness, H , times the slope of the ice surface. For simplicity, we assume that the bedrock is flat. After some manipulations, a one-dimensional ice-sheet model based on the conservation of ice mass, can be formulated as follows

$$\frac{\partial H}{\partial t} = \frac{\partial}{\partial x} \left[D \frac{\partial H}{\partial x} \right] + G(x) \quad (2)$$

where

$$D = kH^{m+1} \left| \frac{\partial H}{\partial x} \right|^{m-1}.$$

The x axis is oriented in the direction of the mean ice velocity in the drainage system, that is, from the interior of the Antarctic continent to the ocean. The mass balance is denoted by $G(x)$. I have used the model formulated by equation (2) in some other studies. (See ref. 6 for details.) Current values for m are within the 2–3.5 range. Here we adopt a value of 2.5. The flow parameter, k , will be chosen such that the present model produces the correct order of magnitude of ice thickness in a typical Antarctic drainage system.

To make the model more tractable, we will now make it zero-dimensional by inserting in equation (2) typical values of the quantities involved. Let the typical ice thickness be H_0 and the typical horizontal scale for ice thickness variations L_0 . To a first approximation, the dynamics of the drainage system can be described by

$$\frac{dH_0}{dt} = -KH_0^{2m+1}L_0^{-(m+1)} + G_0 \quad (3)$$

The constant, K , is not necessarily the same as k . The steady-state ice thickness can easily be found by setting the dH_0/dt to zero. The resulting relation between H_0 and G_0 is displayed in Fig. 1. L_0 has been set to 1,000 km. Curves are shown for $K = 1, 2$ and $6 \text{ m}^{-3/2} \text{yr}^{-1}$, corresponding to $H_0 = 2,311, 2,055$ and $1,712 \text{ m}$ respectively, for $G_0 = 0.17 \text{ m}$ of ice per yr (which is about the average mass balance of the Antarctic Ice Sheet).

To fit the description of ice-flow dynamics given above into a simple linear stochastic model, equation (3) has to be linearized around some reference state. For this purpose, it is natural to use the present state (although we cannot be sure that at present the Antarctic Ice Sheet is close to equilibrium), which will be

denoted by asterisks. We find

$$\frac{dH'_0}{dt} = -K(2m+1)H_0^{*2m}L_0^{-(m+1)}H'_0 + G'_0 \quad (4)$$

A prime denotes deviation from the reference state. According to equation (4), the relaxation time t_R equals $[K(2m+1)H_0^{*2m}L_0^{-(m+1)}]^{-1}$. Values of t_R corresponding to $H_0^* = 2,353, 2,097$ and $1,746 \text{ m}$ are 2,311, 2,055 and 1,712 yr, respectively. Apparently, t_R is not very sensitive to the particular reference state we choose.

At this point, we interpret $G'_0(t)$ as a stochastic process, representing random fluctuations in the mass balance. The quantity H'_0 is assumed to represent deviations of the mean thickness of the Antarctic Ice Sheet (note that this implies that the various drainage systems have the same dynamical characteristics, which seems a reasonable approximation for this analysis). To keep things as simple as possible, we assume that $G'_0(t)$ is a white-noise process, which implies that the process $H'_0(t)$ has a spectrum proportional to $1/(1+\omega^2 t_R^2)$ (red noise). The total variance of $H'_0(t)$ equals $t_R S_G$, where S_G is the (constant) spectral density of the white noise⁴. In practice, a reliable estimate of S_G is best obtained from mass balance measurements that are averaged over some time. If the averaging time is t , the following relation results:

$$\sigma_{H_0} = (t_R)^{1/2} \sigma_G \quad (5)$$

Here, σ denotes standard deviation and the tilde indicates that the mass balance is averaged over t yr. Choosing $t_R = 2,100 \text{ yr}$ (intermediate curve in Fig. 1) and $t_R = 30 \text{ yr}$, we have $\sigma_{H_0} = 250\sigma_G$.

At this point an estimate of σ_G is needed. Figure 2 shows some proxy data on mass balance variations that were readily available and permit an order-of-magnitude estimate of σ_G . The records are inferred from stratigraphical studies at three locations on the Greenland Ice Sheet⁷ and at the South Pole⁸. The data shown suggest a relative standard deviation for 30-yr mean values of roughly 7%. For the Antarctic Ice Sheet with a mean mass balance of 0.17 m ice per yr, this gives $\sigma_G = 0.012 \text{ m}$ ice yr^{-1} . It cannot be expected that precipitation anomalies are uniform over Antarctica. To correct for this we need to know into how many 'independent' regions Antarctica can be divided. At present, no data are available on the typical horizontal scale of accumulation anomalies over the Antarctic Ice Sheet. We therefore arbitrarily assume that five regions exist where

Fig. 2 Time series showing variations in ice accumulation rates, as inferred from stratigraphical studies on the ice of Greenland and Antarctica. The three upper curves are from ref. 7. Variability on time scales smaller than 30 yr has been removed from these curves. The lower curve shows 30-yr mean values of accumulation at the South Pole, computed from data given in ref. 8. Variability is expressed as relative deviation from the mean value.

Fig. 3 Two sea-level records generated by the stochastic model, with a length of 4,000 yr. Values of the constants used: $t_R = 2,100$ yr, $\sigma_G = 0.85$ cm ice per yr.

snowfall fluctuations are uncorrelated. The value of σ_G should then be divided by $\sqrt{5}$, which gives $\sigma_G = 0.0054$ m ice yr^{-1} . The resulting value of σ_{H_0} is about 1.35 m. As the area of the Antarctic Ice Sheet is $\sim 4\%$ of that of the world ocean, the corresponding standard deviation of the sea level amounts to ~ 5 cm. If we would choose the spatial scale of precipitation much smaller, the value of σ_{H_0} would also be smaller. For example, if nine independent regions were present, σ_{H_0} would be about 1 m.

To show more clearly what happens, Fig. 3 provides two examples of sea-level records generated by equation (4). The process $G_0(t)$ was simulated by a random number generator, such that $\sigma_G = 0.008$ m ice yr^{-1} . The records, both spanning, 4,000 yr, show that the major part of the variability is contained in the longer time scales. This is to be expected, because the relaxation time of the ice sheet is of the order of a few thousand years.

The foregoing results clearly demonstrate that stochastic forcing of the Antarctic Ice Sheet by fluctuations in snow accumulation may contribute significantly to variations in global sea level. As revealed in Fig. 3, a sea-level trend of 4 cm in 100 yr can easily be due to the process analysed in this study. Even if local sea-level changes are considered, this is by no means negligible. Other mechanisms creating long-term sea-level variability (like changes in atmospheric wind and pressure patterns, shifts in the oceanic circulation regimes, eustatic effects) lead to changes with the same order of magnitude⁹.

It should be stressed that I have presented here an order-of-magnitude estimate. In the foregoing analysis several uncertainties exist. First, the estimate of σ_G is very crude. A critical survey of all data on accumulation over the Antarctic continent is needed to derive a typical horizontal scale for accumulation anomalies. Another point concerns the very schematic treatment of the dynamics of the Antarctic Ice Sheet. The geometry of Antarctica is rather complicated (large variations in bedrock elevation), so modelling of the ice flow by a zero-dimensional model can only give a crude approximation to reality. The assumption of constant L_0 is a poor approximation for regions where the Antarctic continent is not bounded by deep ocean but by a Antarctic shelf, which makes it possible for the ice sheet to expand horizontally.

In view of these points, perhaps the vertical axis in Fig. 3 should be doubled, or halved. In spite of this uncertainty, however, this study reveals that a substantial part of global sea-level variability may be caused by random forcing of the Antarctic Ice Sheet.

The Caledonian nappes of eastern North Greenland

John Malcolm Hurst* & William Stuart McKerrow†

* Grønlands Geologiske Undersøgelse, Øster Voldgade 10, 1350 Copenhagen K, Denmark

† Department of Geology and Mineralogy, Parks Road, Oxford OX1 3PR, UK

Reconnaissance work in Kronprins Christian Land^{1–7} indicated the presence of one main nappe of late Proterozoic sediments^{2,3} thrust over Lower Palaeozoic platform carbonates similar to Peary Land^{7,8}. Our 2-month helicopter-supported work in 1980 now indicates the presence of three thrust-bounded nappes. The Finderup Land Nappes, which occur in northern Kronprins Christian Land, contain a late Precambrian early Cambrian sequence in thrust contact above Silurian carbonates. The younger Vandredalen Nappe in thrust contact above the Finderup Land Nappes and Silurian carbonates occurs throughout Kronprins Christian Land and contains a thick sequence of late Proterozoic clastics and carbonates. In southern Kronprins Christian Land the Sæfaxi Elv Nappe only contains Ordovician–Silurian carbonates and is in thrust contact below Vandredalen Nappe. The nappes were involved in westward-directed thrusting (>150 km) and are probably a result of continental collision when the northern part of Iapetus Ocean closed in the late Silurian.

On the east coast of Kronprins Christian Land (Fig. 1), a narrow belt of gneisses crops out to the east of Proterozoic sandstones which have been referred previously to the Thule Group^{5,6,9}. Both are probably equivalent to the Proterozoic Independence Fjord Group west of Danmark Fjord¹⁰ (Fig. 1).

The Proterozoic sandstones are intruded by numerous dolerite dykes and sills. West of Danmark Fjord (Fig. 1) an intrusive granophyre in the Independence Fjord Group has yielded a whole-rock Rb-Sr isochron age of $1,230 \pm 25$ Myr (ref. 11) and radiometric dates (minimum age) of interbedded clays give a 1,380 Myr age¹². The Proterozoic sandstones of Kronprins Christian Land are probably of a similar age ($>1,000$ Myr).

The Proterozoic sandstones in Kronprins Christian Land are locally overlain by a conglomerate³ consisting of large (10–100 cm) angular to rounded boulders of Proterozoic sandstone and dolerite. This conglomerate is followed at Hjørnegletscher (E, Fig. 1) by a thin sequence of shallow marine clastics and a stromatolitic dolomite identical to the late Precambrian Fyns Sø Formation of the area west of Danmark Fjord; but at Marmorvigen (C, Fig. 1) the Fyns Sø Formation rests directly on the conglomerate.

The Proterozoic sandstones in Kronprins Christian Land are deformed by strong Caledonian movements (H. F. Jepsen and F. Kalsbeek, personal communication). In Ingolf Fjord the Proterozoic sandstones and the overlying late Precambrian shallow marine clastic sediments are involved in a series of broad anticlines and narrow inclined synclines, showing overriding movement to the west. South of Ingolf Fjord (Fig. 1) these folds are replaced by westward-directed thrusts of Proterozoic sandstone over Fyns Sø Formation. Although the Proterozoic sandstones are in part allochthonous in southern Kronprins Christian Land, they have not moved far, as the thrusts in the south pass laterally into folds in the north.

To the west of the Proterozoic sandstones three large thrust-bounded nappes (Fig. 1) (or groups of nappes) with distinctive

Fig. 2 Stratigraphy and facies distribution of the autochthonous (Foreland⁷ and Proterozoic 'Swell') and allochthonous (Finderup Land Nappes, Vandredalen Nappe and Sæfaxi Elv Nappe) sediments.

Fig. 1 Simplified geological map of Kronprins Christian Land, North Greenland.

stratigraphic sequences are present in Kronprins Christian Land: (1) The Finderup Land Nappes in the north (Fig. 1). These contain sequences of stromatolitic limestone and clastics of the Campanuladal Formation and deformed stromatolitic dolomite of the Fyns Sø Formation overlain by sandstones with *Skolithos* and bioturbated siltstones of the Cambrian Kap Holbæk Formation. (2) The Vandredalen Nappe of central and southern Kronprins Christian Land (Fig. 1). This consists of a thick sequence of turbidites (Rivieradal sandstones^{2,3}) overlain by sands, silts, variegated shales, silts and red limestones (in part Campanuladal Formation) and stromatolitic dolomites (Fyns Sø Formation). This stratigraphic sequence is well exposed on Drømmebjerg (B, Fig. 1), on Nøglefjeldet (D, Fig. 1) and other hills west of Vandredalen. Basal turbidites of the Rivieradal unit also occur on a higher nappe at Marmorvigen (C, Fig. 1) and similar silty turbidites may be on separate nappes in northern Kronprins Christian Land. (3) The Sæfaxi Elv Nappe in south-east Kronprins Christian Land (Fig. 1). This contains a sequence of dolomites with sandstone fissures which have been referred to the Danmarks Fjord dolomite^{2,3}, overlain by Ordovician to ?Silurian black limestones and limy shales of the Centrum Limestone unit.

In addition to these large thrust-bounded nappes, several complex imbricate zones are exposed along their eastern and western margins. To the south-east, near Marmorvigen and along the south-west side of the Sæfaxi Elv (A, Fig. 1), the Vandredalen Nappe rests on the Sæfaxi Elv Nappe and both are thrust over a sequence of Fyns Sø Formation and the conglomerate above the Proterozoic sandstones and dolerites.

The Finderup Land Nappes occur to the north of a large ice cap (Fig. 1) so that its relationship to the Vandredalen Nappe is not clearly exposed. However, the late Precambrian and Cambrian Fyns Sø Formation and Kap Holbæk Formation of the Finderup Land Nappes appear to underlie the Vandredalen Nappe, and this is borne out by the fact that the beds of this nappe are directly in thrust contact with the folded Silurian platform carbonates in Finderup Land.

To the west, the nappes are in thrust contact with the folded sequence of Ordovician and Silurian platform carbonates and

Silurian trough clastics⁷. In the vicinity of the thrusts these Palaeozoic rocks are locally overturned towards the west. If the strike of the fold axes is a direct response to the direction of thrusting, the movement of the Vandredalen Nappe was between 260° and 280°, while in the north the Funderup Land Nappes seem to have travelled towards 310°. To the west and north-west of the nappes, the Palaeozoic beds show asymmetrical folds with steep or overturned north-west or west facing limbs to the anticlines. This disturbed zone stretches for up to 40 km west of the present exposures of the nappes⁷ and, if it is due to deformation by the overriding nappes, it is possibly an indication that the nappes may have formerly extended to Danmark Fjord. Although some steeply inclined reversed faults occur in this region of disturbed Palaeozoic strata, none of the beds has been transported far; they are essentially autochthonous⁷. To the west of Danmark Fjord the same Palaeozoic platform strata are flat-lying and rest undisturbed on earlier Precambrian sediments.

The stratigraphic sequences (Fig. 2) of the large nappes and of the Proterozoic sandstones to the east can only be correlated by: (1) The presence of the stromatolitic dolomites of the Fyns Sø Formation which are known to be late Precambrian on the platform to the west. (2) The presence of *Skolithos* and bioturbated silts which suggests that the uppermost beds of the Funderup Land Nappes are Lower Palaeozoic, and perhaps equivalent to the Lower Cambrian Kap Holbæk Formation of Danmark Fjord. (3) The presence of Ordovician³ and ?Silurian fossils in the Centrum Limestone of the Sæfaxi Elv Nappe. (4) The similarities between the basal lenticular conglomerates resting on the Proterozoic sandstones and those within the Rivieradal unit.

Although none of these individually provides definite age correlations we believe that together they indicate the correlations suggested in Fig. 2.

The Funderup Land Nappes both contain sequences of laminated and cross-bedded sandstones of the Kap Holbæk Formation (with *Skolithos*) above the stromatolitic dolomites of the Fyns Sø Formation. The derivation of these nappes from the south-east suggests that early sliding occurred from an area of uplift to the east of southern Kronprins Christian Land. The folding associated with the northwesterly emplacement of the Funderup Land Nappes has resulted in an extensive area (including both allochthonous and autochthonous rocks) of northern Kronprins Christian Land having strikes at variance with the rest of East Greenland and Kronprins Christian Land in particular.

We agree with Fränkl^{2,3} that the other large nappes are derived from areas east of Kronprins Christian Land. The earlier Sæfaxi Elv Nappe mainly consists of a deep water facies of the Ordovician to ?Silurian Centrum Limestone, containing about 400 m of thin-bedded black limestones and shales. The Sæfaxi Elv Nappe which underlies the Vandredalen Nappe, consists of entirely younger strata. Both nappes have apparently been derived from a source area east of the present day Proterozoic sandstone outcrop (Fig. 1), and both have deeper water facies than equivalent beds on the platform to the west.

The oldest beds on the Vandredalen Nappe are here all assigned to the Rivieradal unit of Fränkl^{2,3}. He named several phyllite, greywacke and sandstone units and considered several nappes were present, but we believe that all the late Precambrian beds below the Campanuladal Formation on this nappe (Fig. 2) are part of a single turbidite and mud sequence on a single nappe which contains several areas (up to ~20 km²) of low-angle isoclinal folds. Because of its tectonic deformation it is not possible to estimate accurate thicknesses, but the lower part of the sequence comprises at least 1,000 m of mudstones (now slates and phyllites) and thin-bedded fine sand turbidites (some rich in calcareous detritus); and the upper part (about 1,500 m) includes thin- to thick-bedded, medium to coarse sand turbidites in addition to several mudstone units and two conglomerate horizons with rounded Proterozoic sandstone and dolerite clasts. It was one of these mass flow resedimented

conglomerates that Fränkl^{2,3} wrongly interpreted as a tillite. These turbidite sequences are followed by several hundred metres of shelf clastics, ~600 m of quartz-rich sandstones, multicoloured shales and red limestones of the Campanuladal Formation and finally by about 200 m of stromatolitic dolomites of the Fyns Sø Formation (Fig. 2).

The presence of Fyns Sø Formation stratigraphically above the Proterozoic sandstones in eastern Kronprins Christian Land (Fig. 2) implies that the Vandredalen Nappe, which also includes the Fyns Sø Formation, must have been derived from east of the Proterozoic sandstone outcrops in the Prinsesse Caroline-Mathilde Alper (Fig. 1). Fränkl^{2,3} first suggested that the sediments contained on this nappe came from the east. It seems probable that the allochthonous thick sedimentary sequences were deposited east of a swell formed by the Proterozoic sandstones which were covered only by thin late Precambrian strata below the Fyns Sø Formation. The conglomerate on the Proterozoic sandstone swell indicates local uplift of the Proterozoic sandstones and this swell may have been the source of the similar rounded clasts in the resedimented conglomerates in the upper parts of the Rivieradal unit.

If, as seems probable, the Funderup Land, Vandredalen and Sæfaxi Elv Nappes are all derived from the margins of the Iapetus Ocean¹³, they would probably have originated east of the gneiss outcrops in eastern Kronprins Christian Land. A southeasterly source for the Funderup Land Nappes would imply a total transport distance of over 150 km, whereas an easterly source for the Vandredalen and Sæfaxi Elv Nappes suggests transport of over 100 km.

The youngest age for the Silurian Profilfjeldet Shale and Turbidites, which were deformed by the overriding nappes, gives a maximum age limit for the Caledonian Orogeny in East Greenland. A precise minimum age of the thrusting in Kronprins Christian Land cannot be established as no late Silurian or Devonian rocks are known. The Profilfjeldet Shale and Turbidites in Kronprins Christian Land may extend into late Wenlock time; the same turbidites in Peary Land extend into the middle Wenlock¹⁴⁻¹⁶. The Profilfjeldet Shale and Turbidites of Kronprins Christian Land and the Peary Land turbidites are mainly derived from the east. In both regions the turbidites succeed a prolonged episode of Ordovician and Lower Silurian platform carbonates¹⁶.

The Caledonian Orogeny in Norway occurs at the same time as in eastern North Greenland. Wenlock rocks are involved in eastward-directed thrusting near Trondheim¹⁷ and Pridoli (Downtonian) conglomerates near Bergen are post-orogenic¹⁸. It seems likely that the Caledonian Orogeny in both Greenland and Norway was due to continental collision in the late Wenlock and Ludlow, closing these northern parts of the Iapetus Ocean. It is also possible that just before collision some local areas of uplift provided a source area for the extensive Silurian turbidites of North Greenland¹⁶ in the late Llandovery and early Wenlock.

We thank N. Henriksen, H. F. Jepsen, F. Kalsbeek and J. S. Peel for critically reading the manuscript. This letter is published with the permission of the director of the Geological Survey of Greenland.

Scale of body pattern adjusts to available cell number in amphibian embryos

Jonathan Cooke

National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, UK

In many embryos, the removal of cells whose descendants would normally have formed entire parts of the body pattern is followed by apparently normal morphogenesis, which implies an ordered readjustment of the activities of the remaining cells before their potentialities become restricted. Special cell lineages cannot underlie the generation and regulation of pattern in such embryos^{1,2}. It is proposed instead that there must be some regulatory communication system in the developing embryo that normally ensures an appropriate spatial pattern of differentiation but which is also able to adjust to the removal, addition or transposition of material at a sufficiently early stage³⁻⁶. Precise models for such a mechanism have recently been suggested⁶⁻¹⁰, and have been tested experimentally¹⁰⁻¹⁴. I have performed surgical manipulations at pre-gastrula embryonic stages in two distantly related amphibian types, *Xenopus* and *Ambystoma*, and report here an assessment of the regulation achieved in terms of pattern proportions. The results are problematical for most current theories of pattern control.

Figure 1a depicts the commitment of cells to form four elements in the medio-lateral dimension of primary mesodermal pattern, during gastrulation and neurulation. Notochord is situated middorsally, and the pattern progresses laterally through somite and pro-nephros to lateral plate for the ventrally centred remainder of the cylindrical cell sheet. The pattern is probably set up in a dorso-ventral time sequence between the onset of gastrulation and the early tailbud stage¹⁵ (that is, 10–30 h, depending on species and temperature), during which about a doubling of cell number occurs along the dimension concerned². About 10^4 cells are involved, and pattern forms across some 1–2 mm (60–100 cells) from dorsal to ventral midlines.

Figure 1b describes the first experimental challenge to the regulatory system, the manufacture of artificially small (few-celled) blastulae that develop into early larval stages without compensatory change in mitotic schedule among the remaining cells. Fate mapping¹⁶ indicates that removed blastomeres would normally have contributed pattern extending from the ventral midline, sometimes to include the entire ventral pair of elements. Figure 1c shows transverse sections of normal and miniature sibling embryos at the late tailbud stage, at which the differentiating pattern was assayed. Embryos were scanned for cell number incorporated into each pattern part, between set positions in the antero-posterior axis of pattern, that is, the anterior end of the pro-nephros and the posterior gut opening as in Fig. 1d. Scans of about 25% of this cell population (using regular subsets of the serial transverse sections and an Abercrombie correction factor) revealed that morphologically small embryos contained 25–60% of the mesodermal cell

Fig. 1 a, The determination of pattern. Density of stippling in the middle mesodermal layer of the gastrula on the left, in transverse section, shows the classically recognized distribution of fates for the cells (in normal development), as they migrate forward (at right angles to the plane of the page) in the form of a coherent, roughly cylindrical, one cell-thick sheet. On the right, the same stippling represents the determined and anatomically visible zones of mesodermal structure at later (post-neurula) stages. Although these structures are solid due to piling up of cells towards the dorsal midline, their proportions in terms of cell numbers probably represent determinative events occurring in the earlier, essentially monolayered situation. Notochord (not) is a small (4%) rod-shaped mid-dorsal population, while paired somite (som) and mid-ventral lateral plate (lpl) zones each comprise ~40% of the cells. The remainder is devoted to the paired pro-nephric (pn) zones lateral to the somites. Determination seems to proceed in a dorso-ventral time sequence, starting with notochord, near the onset of gastrulation, but interactions that accompany grafting, or the co-culture of isolates, can alter development from more ventral regions until neurula stages. ec, ectoderm and neural structures induced from these; mes, mesoderm. b, Size reduction; ventral blastomeres were destroyed by pricking with a fine tungsten needle in an animal-to-vegetal sector, at morula or very large-celled blastula stages, with vitelline membrane and a thin jelly coat remaining on the embryo. Wax-coated dishes were used, containing 20% Niu-Twitty solution adjusted to pH 7.2 with dilute HCl. Dying material loses adhesivity for the healthy blastomeres and is squeezed out through an appropriately positioned slit in the coats, with rounding up and healing of the reduced blastula. Such blastulae were demembrated and kept with normal siblings in 10% Niu-Twitty on glass, until stages of fixation. The healed embryo, which reveals the loss of material in its size and reduced area of dark pigmentation, is shown to scale with the early gastrula section (in the appropriate plane) of a. ∇ marks mid-dorsal in a and b. c, Transverse section of small and normal sibling *Ambystoma* embryos at mid-trunk levels, as scanned in cell number sampling. Counts of nuclear density in the various mesodermal zones in this and the horizontal planes of section reveal that the adaptation of pattern to scale of the tissues is a genuine reflection of the participation of fewer, normal-sized cells in each structure. end, yolky endodermal mass. Scale bar, 1 mm. d, The sampling method. A control and an operated embryo are shown, with sectional levels that bounded the region of the axis used to assay medio-lateral pattern proportions. Sampling thus scanned the mesoderm in a uniform way in each embryo but excluded the head and heart region anteriorly and the tailbud posteriorly, where relatively small proportions of the whole population are involved in morphologically complex situations. Scale regulation definitely occurs in the longitudinal aspect of head and body pattern²⁴. e, eye rudiment; fb, forebrain region; pn, outline of pro-nephros; som, outline of somites; tb, tailbud; pr, protodaeum or original blastopore.

Table 1 Proportions in experimentally small embryos, in the patterns of original polarity in doubly organized embryos, and in control siblings

For the method of scanning patterns, see text and Figs 1a, d and 2b. ND, not differentiated.

* Mesoderm population within controls differed over about a 20% range; the mean being used to derive % values for experimentals within each set. Two significant figures are used throughout, notochord and pro-nephros being small structures, somite and lateral plate large.

number in synchronous control siblings, leading to patterns in which 30–70% of the normal numbers of cells were transected per section in the pattern dimension being considered. Structures form essentially in paired strips or zones between notochord and lateral plate, so that the results of pattern regulation can be expressed as percentages of cells devoted to each structure, relative to those in control siblings.

Cell numbers and the proportions devoted to each pattern element can be assessed in the same way after a second type of operation, the grafting of a dorsal blastoporal lip or 'organizer' region from a donor early gastrula to a site in the ventral marginal zone of a late blastula host^{13,17} (Fig. 2a). In these circumstances the embryo differentiates mesodermal patterns centred round two typical dorsal midline structures, but with full cellular continuity at their lateral interface or plane of mirror symmetry within the original cylinder of the mesodermal mantle. This is because the grafted organizer, while adhering to its own presumptive fate in development as the dorsal midline, has also interacted during gastrulation with the host mesodermal cell population to organize a second axial pattern, embracing ~40% of that population and centred on itself. Cell counts as in Fig. 1d show that the total population within these mirror-symmetric mesoderms is indistinguishable from that in normal siblings at early differentiated stages as studied here (see also ref. 2). Thus, as after the previously described operation, mitotic schedule has been unaltered during cell interactions that adjust pattern.

Table 1 gives pattern proportions in embryos of every set so far examined. Because implanted organizers have only belated opportunity to interact with surrounding material, compared

with the host's original one, most models for the regulatory mechanism can explain how these may involve less than half the host tissue in a pattern of new polarity, as is usually observed. Attention is therefore confined in Table 1 to proportions in the single patterns of miniature embryos and to those in the patterns of original polarity, around the host dorsal midline, in the doubly organized ones. The behaviour within these latter patterns has the most distinctive relevance in assessing models (see discussion below). However, note that when cell numbers are pooled from both patterns for each structure, embryos with two dorsal midlines have only a slight under-representation of 'ventral' parts compared with normal, whereas an obliteration of at least the lateral plate territory might have been expected due to involvement of its tissue in new dorsal parts.

The following points emerge from the data: (1) There is appreciable variation in proportion even among normal sibling embryos, perhaps exceeding that estimated during formation of the proximo-distal pattern of the bird limb¹⁸. Nevertheless, as populations of observations, proportions within the homologous patterns at equivalent stages are remarkably similar within these two distantly related species. (2) Regulation is highly effective in assigning appropriate numbers of the available cells to the four pattern parts. Pro-nephros is relatively the most variable in proportions, in normal development and particularly in very small patterns where it may hardly exist. An apparent tendency for lateral plate to be over-represented in cases where pro-nephros is under-represented may imply that the latter is determined after somite, in tissue which will otherwise become lateral plate. If we therefore estimate pattern as three elements only, that is, notochord, somite and pro-nephros plus lateral plate,

normal and experimentally small embryos become highly comparable populations in terms of proportions. Only notochord, probably determined soon after onset of gastrulation, tends to be rather over-represented where the scale is small. Regulation has been strikingly successful, as obliteration of lateral plate and often of pro-nephros would otherwise have resulted because of the particular cells deleted. A quantitative estimate of the degree of regulation after these experimental challenges is beyond the scope of this study due to the level of variation in the outcome of undisturbed pattern formation. (3) A new organizer, situated ventrally, exerts an active influence in scaling down the pattern formed, with normal polarity around the original dorsal midline, so that both contrapolar versions of the pattern may be almost complete despite sharing a normal-sized tissue sheet during their formation. This requires, as observed, that the pattern centred round the host organizer (as well as that around the new one) has fewer cells in its dorsal parts than do normal versions.

Recent models of control of pattern in early development have arisen mainly from the notion of positional information⁶. This postulates a cell variable or signal, describable as a quantity (for example, morphogen substance concentration), and distributed in a monotonically graded profile between set 'bound-

dary' values across the available tissue for each pattern dimension. Cells are held to interpret this gradient by adopting developmental pathways, or determined states corresponding to particular pattern elements, in response to experience of particular absolute ranges of the signal variable. Thus stated, the idea is a formalism independent of hypotheses as to underlying mechanisms; in Fig. 3 the formalism is used to represent the normal medio-lateral pattern (a) and those actually seen after the two experimental challenges described here (version 3 of b and c). The gradient concept agrees well with the order and polarity shown by the sequences of parts in patterns, and for the

Fig. 2 a, Early gastrula donor and late blastula host viewed from vegetal aspect, presumptive dorsal midline uppermost, to show the implantation of the cell group from the dorsal blastoporal lip into a ventral marginal position at a prepared site. In the control sham operation, which is followed by normal development, the donor site is simply excised and replaced with another, similar cell group. b, Schematic transverse sections (as in Fig. 1a) through a normal embryo, and one having developed a second dorsal axis of pattern through implantation of a dorsal lip, as in a. The axial level is nearer the anterior of the two boundaries indicated in Fig. 1d. Both experimental patterns, though sharing one cell population normal for the embryo's age, have approximately normal proportions. Results in Table 1 include only proportions for the pattern retaining its original polarity in these embryos, that is, the one orientated normally in the right-hand diagram. The effect of the new organizer on the scale of structures in the pattern around the old one is the most troublesome feature for models that would explain the results on the basis of positional information.

Fig. 3 a, A gradient profile which should be taken to represent formally, in scale and proportions, the normal medio-lateral pattern within the mesoderm at determination. The four thicknesses along the baseline represent the extents of zones devoted to the four pattern parts, in terms of cell number within the originally monolayered mesodermal cylinder. Arrows on the ordinate mark threshold values for a positional variable that would set the boundaries between parts on the positional information paradigm. The monotonic gradient is depicted as concave nonlinear because most proposed mechanisms would give such a profile for, say, morphogen concentration after diffusion from a set (organizer) source. The present experimental system offers no evidence for any dynamic second organizing boundary corresponding to a local 'sink'. b, The experimental challenge of small embryonic size. Profile versions 1 and 2 represent expected results on some simple diffusion models (see text), while version 3 shows the observed result, and therefore the gradient profile that any true positional information will have assumed in order to produce it. c, The experimental challenge of double organization in a normal-sized field. Profile and baseline versions 1 and 2 again represent the range of results (from non-interaction, to mutual 'flooding out' of gradient values) expected from the simplest model mechanisms. Version 3 represents the actual behaviour and thus the necessary gradient profile if positional information is to be used. A true positional gradient for this vertebrate pattern dimension would thus have to (1) convey significant local information across much of its extent, and therefore be not extremely nonlinear (note that pro-nephros is both correctly positioned and significantly size-regulated across a range of scales, and is near the midpoint of pattern) and (2) be able to restore its lowest values to cells normally experiencing middle values, when the normal low cells were removed or replaced by a second upper boundary. These are demanding requirements, and alternative theories of pattern control might be more parsimonious, and potentially testable.

phenomenon of the organizer (that is, a pre-determined 'upper boundary' cell group controlling each pattern). But concrete models for positional information mechanisms must be able to explain, or produce during computer simulations, gradient landscapes whose scales and profiles would give the empirically seen results when interpreted as in the formalism.

Models where the organizer is a source at a pre-set level for a diffusing morphogen, and cells elsewhere are sinks, are inadequate. In such schemes, each set of parameters for diffusion, synthesis and destruction of morphogen, implies a gradient or a set time sequence of gradients that occupy particular spaces when embracing a particular concentration range. They would thus lead to profiles between versions 1 and 2 of Fig. 3b and c, corresponding to lack of regulative replacement of ventral pattern, or even to the expansion of dorsal parts due to 'flooding out' of ventral positional values. Models which use reaction-diffusion mechanisms^{8,19,20} are better, as they can produce certain size-regulated gradient profiles, and steepen gradient slopes in systems that have become bipolar in a way that would correspond with present results. Their capacities are stretched to the limits of plausibility, however, by the shape of gradient that would be required here (see Fig. 3 legend) and by the lack of evidence that any region develops 'ventral' organizer properties complementary to those of the dorsal lip. Models where each organizer acts initially to polarize morphogen transport in surrounding tissue, and thus produce its gradient, lead most easily to the necessary gradient profiles. However, there is no indication of structure or physiology that could underlie massive 'uphill' substance transport across embryos.

Alternatively, we can question the hypothesis that cells form the pattern by interpreting a positional gradient alone. Diffusible signal substances made within and specific to each developing pattern part could be involved, acting as size/proportion sensors for the system because the rate at which they are made depends on how many cells are proceeding towards a particular determination, whereas the rate at which they are destroyed depends on total tissue present. These might control the sizes of elements by feedback inhibition that switches cells towards each successive state in a series. The role of each organizer would then be simply to ensure that onset of cell determination *per se*, leading to production of the succession of specific inhibitors, occurs as a coherent (medial to lateral) wavefront across tissue. Demands for sophisticated regulation in such a gradient system would be avoided. This type of model, further described elsewhere^{21,22} makes predictions which are testable and contrast with those of positional information theory²¹, as well as accounting for interaction between organizers in scaling pattern parts (see Fig. 3c); see ref. 23 for discussion of formally similar models.

I thank June Colville for histology, and the MRC for supporting this work.

Sequential functions of the bithorax complex of *Drosophila*

Gines Morata & Stephen Kerridge

Centro de Biología Molecular, Universidad Autónoma de Madrid, Canto Blanco, Madrid 34, Spain

The bithorax genes are a group of homoeotic genes of *Drosophila* whose function is related to the control of segment development. They form a gene complex in which at least seven different loci have been identified¹⁻³. Mutations at each of these loci produce a specific homoeotic transformation whereby a segment is transformed either in part or completely into another³⁻⁵. In embryos completely deficient for the bithorax genes, all the thoracic and abdominal segments resemble mesothoracic segments³. This observation, together with the segmental specificity of the mutant phenotypes, led Lewis³ to suggest a model of genetic control in which the type of development in each segment is specified by the activation of a fraction of the total number of bithorax genes. Thus, lack of activity of the bithorax genes results in mesothoracic development, activation of the *bithorax* (*bx*⁺) and *postbithorax* (*pbx*⁺) genes produces metathorax (anterior and posterior respectively), and activation of these two genes with *bithoraxoid* (*bxd*⁺) produces the first abdominal segment and so on. Although this model explains the genetic and developmental data, it leaves unexplained formation of the prothoracic segment. We now describe two unexpected results: deficiencies for bithorax genes can lead to segments being transformed into prothorax, and there is a temporal sequence in the function of the bithorax system.

We have studied the development of mutants in the locus *Ultrabithorax* which behave as deficiencies for some of the bithorax genes^{1,2,6}. *Trans* combinations of *Ubx* alleles with any of the recessive bithorax pseudoalleles produce the phenotype of the recessive allele in question. As the *Ubx* alleles, like all bithorax deficiencies, are zygotic lethals, they cannot be studied in homozygous adults. Thus, description of the bithorax deletions has so far been restricted to the phenotype before death of embryos or first instar larvae³. Here we have used an alternative approach, whereby we induced clones of cells mutant for *Ubx* in fully viable heterozygous embryos or larvae and examined the phenotypes in the cuticle of adult flies, whose segment patterns are better known and easier to distinguish than those of the embryo or larva. Most of the zygotic lethals are cell viable in the adult cuticle⁷, and mutant clones can be recognized because they are labelled with cuticular markers (see Fig. 1). This method has the advantage that mutant clones can be produced at any desired developmental stage. In most experiments we used the *Minute* technique⁸ to obtain very large clones in which the phenotype can be clearly defined.

We chose the mutation *Ubx*¹³⁰ for most of the experiments because it produces very strong mutant phenotypes over *bx*, *pbx* and *bxd*. To avoid the possibility of effects of other mutants in the *Ubx*¹³⁰ chromosome, the flies used in the clonal analyses carried *Ubx*¹³⁰ over the deletion *Df(3R)P9*. This lethal genotype was rescued by a duplication in the first chromosome that carries all the bithorax genes in wild-type condition (see Fig. 1 legend for technical details).

Clones were induced at 4 ± 2, 7 ± 1, 17 ± 1, 25 ± 1 and 58 ± 8 h after egg laying (AEL). Those induced at 4 ± 2 h AEL will be considered as blastoderm clones, and the rest post-blastoderm.

We examined blastoderm clones all over the body. In dorsal structures they differentiated normally in all segments except the metathoracic and first abdominal ones. In agreement with previous results^{9,10}, clones in the haltere showed a transformation into wing, because *Ubx*¹³⁰/*Df(3R)P9* is deficient for bithorax and postbithorax activities. For reasons discussed

Fig. 1 Details of mitotic recombination to produce clones of cells defective in bithorax activity in $M(1)o^{Sp}Dp(3;1)P115/y w f^{36a}$; $In(3LR)Ubx^{130}$, $Ubx^{130e^s}/Df(3R)P9$ flies. The lethality and mutant phenotype of the combination $Ubx^{130}/Df(3R)P9$ in the third chromosome is rescued by $Dp P115$ which carries wild-type alleles of the bithorax genes. The diagram shows a mitotic recombination event in the first chromosome (the genetic constitution of the third chromosome remains unchanged). Recombination proximal to $Dp P115$ results in the loss of the wild-type bithorax genes in one of the daughter cells. This cell is simultaneously marked with $y w$ and f^{36a} (see ref. 12) and also loses the Minute condition, which confers a growth advantage to the marked cell. The other daughter cell dies due to the presence of $M(1)o^{Sp}$ homozygously⁸. Note that mitotic recombination distal to $Dp P115$ and proximal to f^{36a} produces clones marked with $y w f^{36a}$ that remain wild type for bithorax. We estimate these are 20–25% of the total number of $y w f^{36a}$ clones (see Tables 1 and 2).

elsewhere⁴, thoracic cells cannot differentiate if they are in an abdominal system. Thus, the absence of mutant clones in the first abdominal segment indicates *bxd* transformation. Therefore, the phenotype of the $Ubx^{130}/Df(3R)P9$ clones in the dorsal parts is the one expected for the triple deficiency for *bx*, *pbx* and *bxd*.

However, clones found in the ventral thoracic structures (legs), where bristle patterns can be distinguished as pro-, meso- or metathoracic⁹, showed one important difference compared with those found dorsally—although they all respected the antero-posterior boundary line, the posterior clones of the second (IIP, mesothoracic) and third (IIIP, metathoracic) legs showed a transformation into posterior first (IP, prothoracic) leg (Fig. 2). Clones in the first leg remained untransformed (Table 1). This is the first evidence of transformation into prothorax by a mutation in the bithorax system. Note also that two different segments, mesothorax and metathorax, show the same transformation. The clones in anterior compartments behaved differently—in the first and second legs they remained untransformed but in the third leg they showed a transformation into second. This is the phenotype of mutations in the *bx* locus.

Postblastoderm clones were induced at 7 ± 1 , 17 ± 1 , 25 ± 1 and 58 ± 8 h AEL (Table 1), the last time corresponding to the middle of the second larval period. Clones were found in all body segments and their phenotypes were as described for the blastoderm clones except that at 17 h AEL and at later times IIP and IIIP clones were no longer transformed into IP. Instead, IIP clones remained as IIP and those in IIIP were transformed into IIP; that is, they showed *pbx* phenotype. At 7 ± 1 h AEL some clones showed prothoracic and others a mesothoracic pattern. Thus, the transition period between prothoracic and mesothoracic transformation is at about 7 h of development. These results have been confirmed with nine new *Ubx* alleles induced in our laboratory¹¹ and also with Ubx^1 , which, unlike Ubx^{130} , is a point mutant not associated with any chromosomal rearrangement^{1,2,12}. In this latter case we found four blastoderm clones in IIIP and two in IIP: all transformed into IP. We have also studied the legs of a sample of 32 gynandromorphs (lent by M. P. Capdevila and F. Miñana) in which the male part was mutant for Ubx^1 . The phenotype of the gynandromorph clones was the same as the blastoderm clones.

Thus clones of the same genotype, occupying the same position in the adult structure, show different mutant phenotype depending on the time of clone induction. This can be best explained if the clones are deficient for several functions which are required in a temporal order. It also suggests the existence of an unsuspected gene in the bithorax system, required for the normal development of the mesothoracic and metathoracic posterior legs.

To test whether this gene is different from *pbx* which acts in the same position, we tested whether partial duplications of the

bithorax complex can cover the posterior prothoracic transformations but not the *pbx* transformation. We used $Tp(3)bxd^{100}$ (see ref. 12), a euploid chromosome where some but not all the bithorax genes (*bx*, *Cbx* and *Ubx* but not *bxd* and *pbx*) are transposed to the left arm of the third chromosome. It has a breakpoint between polytene bands 89E2–3 (ref. 12) (within the bithorax region, which extends cytologically from 89E1 to E4) and is mutant for *pbx*. By meiotic recombination we can replace the left arm of this chromosome by a normal one generating a deletion for all transposed genes. This chromosome, $Df(3R)bxd^{100}$, is also mutant for *pbx* and

Table 1 Homoeotic transformations shown by $y w f^{36a}$; $Ubx^{130}/Df(3R)P9$ clones found in the posterior compartments of the legs of $M(1)o^{Sp}Dp(3;1)P115/y w f^{36a}$; $In(3LR)Ubx^{130}$, $Ubx^{130e^s}/Df(3R)P9$ females after irradiation (500 rad) at different times in development

Age at irradiation (h AEL)	No. sides	Phenotype of the clones found in		
		IP leg	IIP leg	IIIP leg
4 ± 2	1,332	IP(22)	IP(13)	IP(14)
7 ± 1	424	IP(7)	IIP(2)	IIP(3)
			IIP(9)	IP(1)
				IIP(2)
				IIIP(1)
17 ± 1	2,030	IP(36)	IIP(36)	IIP(35)
25 ± 1				
58 ± 8				

Data from irradiation at 17 ± 1 , 25 ± 1 and 58 ± 8 h AEL are pooled as there was no difference between them. The actual number of clones observed is shown in parentheses. In IIP and IIIP where homoeotic transformation is seen there is always a fraction of clones that remain untransformed. These are probably the result of mitotic recombination distal to $Dp(3;1)P115$ and proximal to *forked* (see Fig. 1). Dorsal clones induced in this experiment were untransformed except in the metathoracic and first abdominal segments. Clones in the haltere were transformed into wing, anterior clones could completely reproduce the anterior wing compartment (*bx* transformation) and posterior clones could make a posterior wing compartment (*pbx* transformation). In no case did a clone cross the antero-posterior compartment boundary, either in the metathoracic where they produce a transformation or in mesothoracic segment where they have no homoeotic effect. No mutant clones were found in the first abdominal segment. This result is similar to that described⁴ for clones homozygous for Ubx^1 and for bxd^1 induced during the larval period, and probably indicates the transformation of first abdominal histoblast cells into metathoracic or mesothoracic cells. As a control we looked for clones in sib flies of the genotype $Dp(3;1)P115 M(1)o^{Sp}/y w f^{36a}$; $Dp(3;3)P5/In(3LR)Ubx^{130}$, Ubx^{130e^s} where a mitotic event of the type described in Fig. 1 produces $y w f^{36a}$ clones that remain wild type for the bithorax complex. None of the clones found, either in legs (72 in total) or elsewhere in the body, produced homoeotic transformation. To test the remote possibility that transformation into prothorax could be caused by the excess proliferation of M^+ clones which could interact in some unexpected manner with surrounding slowly proliferating Minute cells, we irradiated at 4 ± 2 h AEL embryos of the genotype $Dp(3;1)P115/y w f^{36a}$; $Df(3R)P9/In(3LR)Ubx^{130}$, Ubx^{130e^s} . In this case the $y w f^{36a}$ clones proliferate at the same rate as surrounding cells. Out of five clones in IIP leg, three were clearly transformed into IP and the three clones in IIIP were transformed into IP. Thus the prothoracic transformation does not result from a difference in proliferation rate.

generates an equally strong *pbx* transformation to that of *Tp(3)bx¹⁰⁰/pbx*. We expected the wild-type gene responsible for the prothoracic transformation to be missing in *Df(3R)bx¹⁰⁰* but present in *Tp(3R)bx¹⁰⁰*, in which case blastoderm clones of the genotype *Df(3R)bx¹⁰⁰/Ubx¹³⁰* would show prothoracic transformation whereas blastoderm *Tp(3R)bx¹⁰⁰/Ubx¹³⁰* clones would not. In both genotypes post-blastoderm clones should show a *pbx* phenotype.

The experiments were conducted by the same method as those described for *Df(3R)P9*, substituting *Tp(3)bx¹⁰⁰* or *Df(3R)bx¹⁰⁰* for *Df(3R)P9*. The results are shown in Table 2 and they are exactly as expected: the prothoracic transformation is absent in *Tp(3;3)bx¹⁰⁰/Ubx¹³⁰* clones but present in

Table 2 Type of homoeotic transformation shown in the posterior compartments of the legs by blastoderm clones of the genotypes indicated

Genotype	No. sides	Phenotype of blastoderm clones found in		
		IP leg	IIP leg	IIIP leg
<i>Df(3R)bx¹⁰⁰/Ubx¹³⁰</i>	910	IP(7)	IP(6) IIP(1)	IP(10) IIIP(1)
<i>Tp(3;3)bx¹⁰⁰/Ubx¹³⁰</i>	976	IP(7)	IIP(8)	IIP(6) IIIP(1)

Clones were induced after irradiation (500 rad) at 4 ± 2 h AEL in female embryos of genotype *y w f^{36a}/M(1)0^{5p}Dp(3;1)P115; In(3LR)Ubx¹³⁰, Ubx¹³⁰e⁺/Df(3R)bx¹⁰⁰* in the first case and *y w f^{36a}/M(1)0^{5p}Dp(3;1)P115; In(3LR)Ubx¹³⁰, Ubx¹³⁰e⁺/Tp(3;3)bx¹⁰⁰* in the second. Both genotypes are phenotypically wild type for bithorax. The number of clones found is shown in parentheses. Some clones in legs IIP and IIIP did not show transformation probably for the reason mentioned in Fig. 1 and Table 1. Post-blastoderm clones of both genotypes showed mesothoracic transformation.

Fig. 2 Homoeotic transformation shown by *y w f^{36a}; Ubx¹³⁰/Df(3R)P9* clones (below the dotted line) in the posterior compartment of the second leg. *a*, Blastoderm clone showing transformation into posterior first leg; *b*, post-blastoderm clone not showing transformation. Note the difference in the bristle pattern of the two clones. *c* Shows a blastoderm clone in the posterior first leg for comparison.

Df(3R)bx¹⁰⁰/Ubx¹³⁰. Therefore, the gene responsible for the prothoracic transformation is present in the transposed fragment and is not associated with *pbx*. It was previously thought that lack of bithorax function results only in mesothoracic development³. However, these results show the existence of a gene of the bithorax system that, if mutant, transforms the posterior compartments of both mesothoracic and metathoracic legs into prothorax. The gene is located to the left of *pbx* and included in the fragment of the bithorax complex missing in *Df(3R)bx¹⁰⁰*. Its function is necessary for the development of the mesothoracic and metathoracic segments and its realm of action is defined by the antero-posterior compartment boundary. Like the genes *bx*, *pbx* and *bx^d*, this one also is inactivated by *Ubx* alleles. Following Lewis' nomenclature we propose to call this gene *postprothorax* (*ppx*). Its period of function differs from that of *bx* and *pbx*; *Ubx¹³⁰/Df(3R)P9* clones show prothoracic transformation only if induced before 7 h AEL. Clones of the same genotype induced at 17 h AEL develop as mesothorax. Thus, *ppx* function is needed in early development but is dispensable thereafter, unlike *bx* and *pbx* whose functions are needed until the end of the larval period⁴.

The two sets of genes seem to act sequentially: in the posterior metathoracic leg there is an early requirement for the *ppx* gene activity, which blocks prothoracic development and directs the cells to the mesothoracic pathway. A few hours later *pbx*⁺ gene function is required, preventing mesothoracic and allowing metathoracic development. Thus the final developmental route taken by the posterior metathoracic leg is specified by the combined sequential function of *ppx* and *pbx*. This suggests a temporal mechanism in the genetic process of thoracic and abdominal determination. Each segment would undergo a succession of determinative steps, each genetically implemented by the activation or inactivation of a particular homoeotic gene. The final development of each segment would be specified by a unique combination of active genes.

The *ppx* transformation affects only ventral structures (legs) whereas *bbx* (and *bx*) transforms the dorsal (halteres) as well. We cannot explain this difference but a common feature of all the homoeotic mutants producing transformation into prothorax is that this transformation is shown exclusively in the legs (for example *Polycomb* (*Pc*)¹³, *Extra sex comb* (*Scx*)¹³ and *Multiple sex comb*¹⁴).

Although our results only show evidence for a posterior prothoracic transformation, the existence of mutations like *bx* and *pbx*, that produce homologous mesothoracic transformations in anterior and posterior compartments respectively, suggests the existence of an 'anterior' prothoracic gene which, when defective, would transform the anterior meso- and metathorax into anterior prothorax. This hypothetical gene need not be in the bithorax complex.

The existence of prothoracic transformations produced by bithorax mutants apparently contradicts with results of Lewis³. He finds that embryos homozygous for *Df(3R)P9* show a transformation of all segments into mesothorax. Our explanation for this discrepancy is that ventral landmarks used by Lewis

(denticle belts) are all anterior and the prothoracic transformation could only be seen in the posterior compartments.

We thank Jim Kennison, Peter Lawrence, Dan Lindsley, Pedro Ripoll and Lenny Robbins for comments, Rosa González for technical help, and Victoria Lafita and Ernesto Sánchez-Herrero for typing the manuscript. S.K. is supported by an EMBO fellowship.

Immobilization of concanavalin A receptors during differentiation of neuroblastoma cells

§Laboratory of Biochemical Genetics, NHLBI, National Institutes of Health, Bethesda, Maryland 20014, USA

Neuroblastoma cells serve as a useful model of neuronal development because compounds such as dimethyl sulphoxide (DMSO) and dibutyryl cyclic AMP cause them to undergo a process of controlled differentiation in tissue culture, during which they can extend long processes, develop characteristic excitability mechanisms, synthesize neurotransmitters and form synapses^{1–3}. We have used the technique of fluorescence photobleaching recovery to study the lateral mobility of cell-surface constituents during the differentiation of neuroblastoma clone N1E-115 cells. The concanavalin A (Con A) binding sites appear as discrete patches distributed over the entire cell surface and exhibit lateral mobility in undifferentiated cells comparable with that of surface glycoproteins of other cells. After induction of differentiation, however, the vast majority of Con A binding sites become immobilized, and we present data which suggest that the mechanism of this immobilization may involve linkage to the internal actin network.

Cells of the adrenergic clone N1E-115 were grown and passaged in Dulbecco's modified Eagle's medium supplemented with 2.5% fetal bovine serum, in an atmosphere of 10% CO₂, 90% air, and replated in 35-mm plastic tissue culture dishes either with ('differentiated') or without (control) 2% DMSO. Cells were washed twice with Hank's balanced salt solution before labelling with the lectins succinyl Con A or wheat-germ agglutinin (WGA), which had been conjugated with tetramethylrhodamine isothiocyanate (E-Y Laboratories), or with the lipid analogue 3,3'-dioctadecylindocarbocyanine iodide (diI). Observation was with a Zeiss Universal microscope equipped with a $\times 63$ 1.25 n.a. water immersion lens and epifluorescence illumination.

Lateral mobility was evaluated quantitatively by the fluorescence photobleaching recovery technique^{4,5}, in which a laser beam is used as the excitation source and is sharply focused on a small area (1 μm^2) of the membrane of a labelled cell. A brief intense pulse then irreversibly bleaches 40–70% of the fluorophore within that region. Monitoring the recovery of fluorescence, as unbleached molecules subsequently diffuse into the bleached region, allows calculation of the relative amounts of mobile and immobile fluorophore and the diffusion coefficient of the mobile fraction.

Con A binding sites were distributed in patches over the entire cell surface, including soma, processes and growing tips. This clustering was apparent even if the cells were prefixed with 3.7% formaldehyde, or labelled at 4 or 37 °C. No bulk movement or capping of receptors was observed. Fluorescence intensity was dramatically reduced if labelled cells were subsequently

Fig. 1 Recovery of fluorescence after photobleaching. Cells were labelled with 12.5 $\mu\text{g ml}^{-1}$ rhodaminated succinyl Con A at room temperature for 20 min, and then washed twice with the balanced salt solution. Each point represents the per cent recovery of fluorescence after bleaching a site on cells incubated in control conditions (a) or after treatment with 2% DMSO (b) for the number of days indicated. c, The percentage of measurements showing immobilized Con A receptors (<10% recovery of fluorescence after photobleaching) when exposed to control (○) and differentiating (●) conditions for the number of days indicated.

Table 1 Glycoprotein and lipid probe mobility on neuroblastoma cells

Probe	Treatment	Immobile sites (%)	$D \times 10^{10}$ ($\text{cm}^2 \text{s}^{-1}$)	Mean fractional recovery (%)
Succinyl Con A	Untreated (51)	18	1.3 ± 1.0	36 ± 28
	DMSO (all sites) (56)	79	—	7 ± 15
	Soma (31)	85	—	8 ± 20
	Hillock (13)	69	—	6 ± 8
	Process (12)	83	—	4 ± 8
	Dibutyl cyclic AMP (7)	71	—	5 ± 10
	Cytochalasin B DMSO (13)	23	1.6 ± 0.8	23 ± 18
	No DMSO (10)	10	1.0 ± 0.7	28 ± 20
	Colcemid DMSO (8)	75	—	10 ± 16
	No DMSO (10)	30	1.4 ± 1.0	29 ± 21
WGA	Untreated (12)	50	—	12 ± 12
	DMSO (14)	64	—	12 ± 13
	Cytochalasin B DMSO (14)	50	—	14 ± 12
diI	Untreated (10)	0	101 ± 20	—
	DMSO (9)	0	122 ± 50	—

Cells were labelled with $12.5 \mu\text{g ml}^{-1}$ succinyl Con A (10–20 min), $12.5 \mu\text{g ml}^{-1}$ WGA (20 min) or $10 \mu\text{g ml}^{-1}$ diI (3 min) and washed twice with the balanced salt solution. Treatment with DMSO was for 2–14 days, and with dibutyl cyclic AMP for 7 days. Cytochalasin B was used at a concentration of $10 \mu\text{g ml}^{-1}$ during the preincubation (30 min) and left in the dish during measurements. Colcemid was used at a concentration of $0.4 \mu\text{g ml}^{-1}$ during the preincubation (30 min) and then removed by washing. To achieve satisfactory signal-to-noise ratio, an individual diffusion measurement of diI often involved adding several successive recoveries from repeated bleaches at a single site. The immobile sites are those which showed less than 10% recovery after photobleaching. The diffusion coefficient (D) and mean fractional recovery are shown as mean $\pm$ s.d. and were calculated using the theory developed by Axelrod *et al.*⁵. D is related to the half-time for recovery, $t_{1/2}$, by $D = \gamma\omega^2/(4t_{1/2})$ where γ is a factor that takes into account the extent of bleaching and ω is the focused laser beam radius at the e^{-2} intensity point. The fractional recovery is the per cent of fluorescence that returns after bleaching of a site. The number of sites measured under each treatment is given in parentheses.

incubated with 50 mM α -methyl mannoside, demonstrating that the Con A was binding to sites on the surface of the cells and had not been internalized.

Most Con A receptors were mobile on control cells (Fig. 1), with a diffusion coefficient of $1.3 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$, comparable with that measured for membrane proteins in many cells⁴. In control cells neither the number of immobile sites nor their diffusion coefficient changed for periods of growth of up to 2 weeks (by which time cells had reached confluency).

However, during differentiation induced by DMSO, we found a dramatic reduction in the number of sites at which receptors were mobile (Fig. 1). This effect was seen within 36 h of the beginning of treatment and persisted throughout the 2-week study period, by which time the cells had extended long processes. There was no accompanying segregation of Con A receptors to either soma or processes, nor, as shown in Table 1, did mobile sites persist in any particular region of the cell. It is clearly possible that in conditions that leave most receptors mobile, more subtle changes in the diffusion coefficient might be found on different parts of the cell⁶. WGA receptors were also distributed over the entire cell surface but showed no evidence of a change in the number of immobile sites during differentiation (Table 1). Treatment of cells with 1 mM dibutyl cyclic AMP for 1 week also induces morphological and electrophysiological maturation², and caused a similar degree of immobilization of Con A binding sites. These effects are unlikely to be related

simply to the lowered rate of cell division seen with differentiating agents because de Laat *et al.* have shown protein diffusion to be slowest during mitosis⁷. Furthermore, serum withdrawal markedly slowed cell division⁸ and induced neurite extension but did not reduce the mean fractional recovery or increase the number of immobile sites (all sites were mobile, $n = 6$).

Further investigation suggested that the cytoskeleton contributed to the developmental immobilization. Although restrictions of mobility might conceivably derive from changes in 'fluidity' of membrane lipid^{9,10}, the diffusion coefficient of the lipid probe diI was not significantly different in control and DMSO-treated cells (Table 1), suggesting that changes in the lipid environment were not responsible. On the other hand, as shown in Table 1, dissociation of components of the cyto-

Fig. 2 Growth cone (a) and cell body (b) of a neuroblastoma cell treated with 2% DMSO, washed in balanced salt solution, labelled with succinyl Con A, fixed for 30 min in 3.7% formaldehyde and then labelled with $0.5 \mu\text{g}$ of NBD-phalloidin in 0.5 cm^3 of balanced salt solution for 30 min and washed twice. It shows the correlation of the internal actin network, labelled with the NBD-phalloidin (top) and the external Con A binding sites (middle). Bright field is shown at the bottom. In other experiments cells were labelled singly with either NBD-phalloidin (after fixation) or Con A (both before and after fixation) alone and the same patterns were observed. The NBD-phalloidin did not label unfixed cells, even if incubated for 48 h. Fluorescence photomicrographs were taken using epifluorescent illumination and standard Zeiss filters for rhodamine or fluorescein (for the NBD-phalloidin). Control experiments revealed no 'bleed through': rhodaminated succinyl Con A was not visible at the NBD excitation wavelength, and the NBD was not visible at the rhodamine excitation wavelength. Scale bar, $10 \mu\text{M}$.

skeleton reversed the developmental immobilization. Most dramatic was the effect of cytochalasin B, an agent that disrupts microfilaments, and which reduced the percentage of immobile sites in differentiated cells from 79 to 23%. Incubations with colcemid for 30 min reversibly disrupt microtubules in these cells¹¹ but only slightly increased the mobility of Con A receptors, suggesting a lesser role for microtubules in the immobilization process. Prolonged treatment (90 min) did increase the mobile fraction, but cells in these conditions had lost all processes and many floated free. WGA receptors are immobilized by cytochalasin-insensitive mechanisms on both differentiated and undifferentiated cells. Thus, there are apparently constraints in the mobility of some surface molecules which are distinct from those which act on Con A receptors.

We pursued this suggestion of cytoskeleton-membrane interaction by correlating the distribution of internal actin with that of Con A receptors. A fluorescent derivative of the mushroom toxin phalloidin has recently been demonstrated to bind actin specifically and with high affinity¹². This 7-nitrobenz-2-oxa-1,3-diazole phalloidin (NBD-phalloidin) does not seem to alter the distribution of actin filaments (by comparison with staining with anti-actin antibodies)¹³ even though the closely related toxin phalloidin can cause conversion of G- to F-actin¹⁴. The actin network, as revealed by NBD-phalloidin, is concentrated at the cell periphery and growing tips (Fig. 2). This punctate peripheral distribution was similar in control and DMSO-treated cells, and is identical to the distribution of actin described using anti-actin antibodies¹⁵. Photographs of the ConA receptors on the same cell in the same focal plane show the remarkable correlation of Con A binding sites with regions of actin accumulation. This correlation was noted on surfaces on the cell soma, along the processes and on the growth cone. WGA binding sites, on the other hand, often were not associated with actin.

Interactions between actin and cell membrane receptors are thought to underlie capping in lymphocytes and other cells¹⁶⁻¹⁸ and to guide anisotropic movements on cell surfaces¹⁹. In some systems, there is evidence for linkage proteins that mediate cytoskeleton-membrane interactions²⁰. During morphological differentiation of neurones, the immobilization of selected cell-surface components, under the influence of genetic and environmental cues, may underlie acquisition of structural asymmetry and could serve not only to guide directed axon outgrowth, but also to enhance anatomical registration of pre- and postsynaptic structures.

We thank L. Barak for his gift of NBD-phalloidin, A. Waggoner for his gift of diI and M. Nirenberg, R. Blumenthal and P. G. Nelson for their support and the use of their facilities.

Role of cyclic AMP in a serotonin-evoked slow inward current in snail neurones

Philippe Deterre*, Danièle Paupardin-Tritsch*, Joël Bockaert† & Hersch M. Gerschenfeld*

One model of synaptic transmission suggests¹ that transmitters modify postsynaptic permeability through the intermediary of cyclic AMP. Thus, serotonin (5-hydroxytryptamine) evokes in molluscan neurones a decrease in a voltage-dependent K^+ conductance^{2,3} which in turn generates a slow inward current when studied in steady voltage-clamp conditions³. The serotonin-induced increase of the plateau phase of the spike of an *Aplysia* sensory neurone can be mimicked by both intracellularly injected cyclic AMP and extracellularly applied phosphodiesterase inhibitors⁴, suggesting that cyclic AMP mediates the effect. We have tested whether a similar mechanism could account for the serotonin slow inward current in identified snail neurones and have found that the intracellular injection of cyclic AMP, but not of cyclic GMP or 5'-AMP, evokes a slow inward current showing similar voltage dependence, inversion potential and ionic properties to the serotonin slow inward current. Phosphodiesterase inhibitors at low concentrations (1-20 μ M) potentiate the serotonin slow inward current and at higher concentrations evoke by themselves an inward current, partially or totally occluding the serotonin and cyclic AMP currents. Finally, we have found that in homogenates of pooled identified snail neurones serotonin stimulates the adenylate cyclase, increasing its activity by 50-100%.

The experiments were carried out on identified neurones of the viscerio-abdominal ganglionic mass of *Helix aspersa* (cells F5, F6, E1, E2, E15, E17 of Kerkut *et al.*⁵). The ganglia were isolated in a chamber and continuously bathed in circulating saline of the following composition in mM: NaCl 120, KCl 5, CaCl₂ 6, MgCl₂ 3.5, HEPES 10 at pH 7.4. The identified neurones were impaled with double-barrelled microelectrodes connected to a voltage-clamp circuit⁶. Serotonin was applied iontophoretically or through the circulating bath solution. Tetraethylammonium (TEA) ions, Cs⁺, EGTA, cyclic AMP, cyclic GMP and 5'-AMP were injected intracellularly by passing appropriate inter-barrel currents⁷ between the barrels of double microelectrodes. One of the barrels was filled with TEA-Cl (1 M), CsCl (1 M), EGTA (0.5 M) or a 0.1 M solution of a monosodium compound of one of the nucleotides and the other with 3 M KCl. In the experiments in which both cyclic AMP and a channel blocker (or EGTA) were intracellularly injected by passing inter-barrel currents in the same cell, assemblies of three intracellular pipettes were used. NaCl was replaced in the saline by either Tris-Cl or sucrose, keeping the molarity constant. CaCl₂ in the saline was replaced by CoCl₂. When the extracellular Ca²⁺ concentration [Ca²⁺]_o was increased or TEA-Cl added to the saline, the molarity was kept constant by reducing the NaCl in the medium. Phosphodiesterase inhibitors (isobutyl methylxanthine, IBMX; RO 20-1724) were added to the circulating saline. Adenylate cyclase activity was assayed in pools of 40 identified snail neurones dissected out from 15 ganglia, according to the technique of Levitan⁸ slightly modified.

Figure 1A compares the effects of extracellular application of serotonin and the intracellular injection of cyclic AMP in the same snail neurone. When the membrane potential was held between -100 and -30 mV, serotonin evoked a biphasic inward

Fig. 1 A, Voltage-clamped snail neurone. The iontophoretic applications of serotonin (5-HT) (a-d) and the intracellular injections of cyclic AMP (cAMP) (e-h) were performed in sequence while holding the cell at different potential levels (centre). Note that the early small outward current evoked by serotonin in a (due to the activation of other receptors⁹) is not present in the cyclic AMP response (d). **B,** *I-V* curve relating the net currents evoked by iontophoretic applications of serotonin (▲) and intracellular injections of cyclic AMP (□) in a snail neurone bathed in a saline containing 30 mM TEA to suppress other components of the membrane conductance and of the serotonin response. The steady-state *I-V* curves were first obtained by stepping the voltage from a holding level (+10 mV) to different levels of potential between -90 and +50 mV and measuring the current 1 s after the onset of the pulse. The net currents evoked by serotonin and cyclic AMP were obtained by subtracting the steady-state curves obtained with serotonin and cyclic AMP from the control steady-state curves.

current (Fig. 1A, c, d) which, as previously shown^{3,9}, was associated with an increase in Na^+ conductance. At levels more depolarized than -30 mV (Fig. 1A, a, b), serotonin evoked a much slower inward current which showed a latency of 3-5 s. In contrast, no effect of intracellularly injected cyclic AMP was observed when the cell potential was held between -30 and -100 mV (Fig. 1A, g, h), but at potentials more depolarized than -30 mV (Fig. 1A, e, f) cyclic AMP also evoked a slow inward current whose amplitude increased with further

depolarization (Fig. 1A, e) in parallel with the serotonin response. The only difference between the two responses was that the cyclic AMP response never showed other components resulting from the activation of other serotonin receptors such as in Fig. 1A, a.

The current-voltage (*I-V*) curve of Fig. 1B relates the normalized values of the net currents evoked by either extracellularly applied serotonin (full triangles) or intracellularly injected cyclic AMP (squares) to the levels at which the voltage was stepped for measuring the currents. It is clear that the same *I-V* curve fits perfectly the values of the net currents evoked by either serotonin or cyclic AMP. Both currents show a maximal value at about +10 mV and an inversion potential at about -55 mV. Even if the inversion potential of both responses differed from the potassium potential, E_K (-75 mV in the snail neurones bathed in the same saline), it was sensitive to changes in the extracellular K^+ concentration. Intracellular injection of either 5'-AMP or cyclic GMP inside the same identified snail neurones had no effect.

The fact that a cyclic AMP-induced slow inward current was only seen in cells that exhibited a serotonin slow inward current, together with the similarity of the *I-V* curves of the two slow inward currents, suggests that these currents reflect the same conductance change. To test this hypothesis we compared the ionic sensitivity and pharmacology of the two currents. Neither the serotonin response nor the cyclic AMP response was affected by the replacement of two-thirds of the extracellular NaCl by either Tris-Cl or sucrose or by the presence of 30 mM TEA in the extracellular medium. The amplitude of both responses increased in parallel when $[\text{Ca}^{2+}]_o$ was increased up to 20 mM. Moreover, replacement of the $[\text{Ca}^{2+}]_o$ with Co^{2+} generated by itself an inward current and occluded the effects of both serotonin and cyclic AMP while intracellular injection of the K^+ -channel blockers TEA and Cs^+ , which evoked an inward current by themselves, also blocked the slow currents evoked by both serotonin and cyclic AMP. As was also the case for the serotonin slow inward current, EGTA intracellular injection had no blocking effect on the cyclic AMP slow inward current. Finally, when serotonin application evoked a maximal slow inward current it occluded any further effect of cyclic AMP and vice versa. Table 1 compares the properties of both slow inward currents.

These results indicate that the extracellular application of serotonin and the intracellular injection of cyclic AMP both induce slow inward currents which reflect a decrease in the same voltage-dependent and $[\text{Ca}^{2+}]_o$ -sensitive K^+ conductance.

Fig. 2 A, Potentiating effect of IBMX on the serotonin slow inward current. a_1 , a_2 , Control serotonin slow inward currents obtained with the same iontophoretic current by varying the duration of the iontophoretic pulse a_3 , a_4 Responses to the same iontophoretic serotonin pulses as in a_1 , a_2 but in the presence of 20 μM IBMX in the extracellular medium. **B,** In another snail neurone, extracellular application of 100 μM IBMX evokes by itself an inward current and occludes the effects of the application of serotonin and cyclic AMP.

The next question is whether cyclic AMP mediates the effects of serotonin on the K^+ conductance whose decrease gives rise to the serotonin slow inward current. If a causal relationship exists between serotonin and cyclic AMP effects, it could be expected that the inhibitors of phosphodiesterase, the enzyme involved in the inactivation of cyclic AMP, should potentiate the response to serotonin. The results of our experiments were somewhat more complex. When IBMX was added to the bath in a concentration which, according to the cell, varied between 1 and 20 μ M, it caused, as expected, an increase in both amplitude and duration of the serotonin slow inward current (Fig. 2A, compare a_1 with a_3 and a_2 with a_4). However, at higher doses (up to 100 μ M), IBMX itself evoked an inward current which occluded both the serotonin and cyclic AMP responses (Fig. 2B). Similar effects were observed when using other methylxanthine-type phosphodiesterase inhibitors such as theophylline and with non-xanthine compounds such as RO 20-1724.

Our experiments suggest that the serotonin slow inward current results from the stimulation of an adenylate cyclase by

Table 1 Comparative properties of slow inward currents evoked by serotonin I_{S-HT} and cyclic AMP I_{cAMP}

	I_{S-HT}	I_{cAMP}
Increase of $[Ca^{2+}]_0$	Increase	Increase
Decrease of $[Ca^{2+}]_0$	Decrease	Decrease
Co^{2+}	Block	Block
Intracellular TEA	Block	Block
Intracellular Cs	Block	Block
Intracellular EGTA	No effect	No effect

serotonin. The latency of the serotonin response and the potentiating effects of the phosphodiesterase inhibitors favour such a view because it can be assumed that there is a basal activity of the cyclase and that the higher concentrations of IBMX could evoke increased accumulation of cyclic AMP which in turn would evoke a maximal decrease in K^+ conductance and thus occlude the responses to further extracellular application of serotonin or intracellular injection of cyclic AMP.

This hypothesis was supported by assays of adenylate cyclase activity. The adenylate cyclase activity of homogenates of pooled identified snail neurones, measured by the production of cyclic AMP from ATP during 30-min periods, was 151 ± 12 fmol (mean $\pm$ s.e.m. for triplicates) in basal conditions and 283 ± 4 fmol in the presence of 10 μ M serotonin, that is, serotonin increased the enzyme activity by 87%.

In conclusion, the present results suggest that the decrease in voltage-dependent K^+ conductance associated with the slow inward current evoked by serotonin in snail neurones is actually due to serotonin stimulation of the adenylate cyclase activity. In a larger context these results, together with other effects of serotonin on molluscan neurones probably mediated by cyclic AMP^{6,10}, support the idea that some synaptic actions may also depend on the activation of a second messenger system¹.

Sertoli–Leydig cell communication via an LHRH-like factor

R. M. Sharpe*, H. M. Fraser*, I. Cooper* & F. F. G. Rommerts†

*MRC Reproductive Biology Unit, Centre for Reproductive Biology, 37 Chalmers Street, Edinburgh EH3 9EW, UK

†Department of Biochemistry, Division of Chemical Endocrinology, Erasmus University, Rotterdam, The Netherlands

The primary function of the testosterone secreted by Leydig cells is the maintenance of spermatogenesis and hence fertility¹. This action of testosterone is mediated by the Sertoli cells which nourish and support the developing spermatozoa². As normal Sertoli cell function is so critically dependent on normal Leydig cell function, a regulatory influence of the Sertoli cells on the Leydig cells has been suggested^{3,4}. Indeed, follicle-stimulating hormone (FSH), which acts only on Sertoli cells⁵, can also cause profound changes in Leydig cell function^{6–8}, although how this is effected is unknown. We recently hypothesized that the Sertoli cell might be the source of a luteinizing hormone releasing hormone (LHRH)-like factor which we detected in the interstitial fluid surrounding the Leydig cells⁹. As injected LHRH agonists cause impairment of gonadal function^{10–13} and directly inhibit FSH-induced changes in Leydig cell function¹⁴ through specific membrane receptors^{15–17}, this 'LHRH-like' factor has all the correct credentials for the postulated messenger between the Sertoli and Leydig cells³. Here, we strengthen this case by demonstrating that seminiferous tubules from both the rat and the stump-tailed macaque (*Macaca arctoides*) contain a factor which has LHRH-like receptor-binding and biological activity *in vitro*, but which is immunologically distinct from native LHRH. We have also shown that this factor is secreted *in vitro* by cultured rat Sertoli cells.

Because of their ease of preparation and the specificity and affinity with which they bind radiolabelled LHRH agonists^{15–17}, isolated rat Leydig cells provide a simple, sensitive and precise radioreceptor assay for LHRH-like factors⁹. We have used this method to demonstrate that crude acid extracts of rat seminiferous tubules contain a factor which cross-reacts in parallel with unlabelled LHRH agonist (Fig. 1), whereas similar extracts of liver are inactive (data not shown). However, such crude extracts contained large amounts of protein (which may interfere in the receptor assay) and their potency decreased rapidly and progressively during storage at -20°C . An extract was therefore prepared which excluded proteins, based on methods for the extraction of native LHRH from the hypothalamus¹⁸. This acid/ethanol extract also gave parallel displacement curves to LHRH agonist in the receptor assay (Figs 1, 2), although more potent preparations tended towards non-parallelism when suppressing binding by 75% or more (see Fig. 3 and Fig. 1 legend). Acid/ethanol extracts of rat seminiferous tubules or stump-tailed macaque testis gave parallel displacement in the receptor assay and both stimulated ($P < 0.01$ and $P < 0.02$) the release of LH from rat hemipituitaries *in vitro* (Fig. 2).

Although the Sertoli cell seemed the most likely source of this LHRH-like factor, this was not certain as the seminiferous tubule preparation contained both germ cells and Sertoli cells, and was contaminated with some adherent Leydig cells. To resolve this problem we tested medium from Sertoli cell cultures. When assayed without dilution, this medium showed negligible LHRH-like activity in the receptor assay but after acid/ethanol extraction, which effectively concentrated it by a factor of 30, LHRH-like activity was clearly detected, two separate extracts giving dose-response curves parallel to LHRH agonist (Fig. 3). The specificity of this displacement can be judged by the fact that the Sertoli cell culture medium (SCCM)

extract and a rat seminiferous tubule extract gave only minor, although significant ($P < 0.05$), displacement in a Leydig cell human chorionic gonadotropin (HCG)-receptor assay which was run in parallel (Fig. 3). Interestingly, previous workers testing SCCM for inhibin-like activity reported the presence of a small molecule which stimulated pituitary LH release *in vitro*^{19,20}, and this probably corresponds to the LHRH-like factor which we have detected by receptor assay.

The nature of this LHRH-like factor produced by the Sertoli cells is unknown. It is clearly different from native LHRH, as rat seminiferous tubule extracts were largely inactive in an LHRH radioimmunoassay (Fig. 4). However, in a radioimmunoassay which we have developed using an antiserum raised against the LHRH agonist, seminiferous tubule extracts gave displacement

Fig. 1 Displacement of the binding of ^{125}I -LHRH agonist ((D-Ser-r-bu⁶, des-Gly-NH₂¹⁰) LHRH ethylamide) to dispersed Leydig cells by unlabelled LHRH agonist and rat seminiferous tubule (S-tubule) extracts. The methods used for the preparation of Leydig cells¹⁶ and the radioreceptor assay procedure were as described previously^{9,16}, except that the volumes used were 0.15 ml dispersed cells, 0.2 ml sample/standard and 0.05 ml ^{125}I -LHRH agonist; all samples and standards were run in duplicate. To prepare crude seminiferous tubule extracts, decapsulated testes from adult Sprague-Dawley rats were dispersed with collagenase²⁹, the isolated Leydig cells removed¹⁶ and the tubules washed three times with 50 ml 0.9% saline. After the last wash the tubules were centrifuged for 10 min at 1,000g, the supernatant discarded and the precipitated tubules homogenized in 0.1 M acetic acid (0.3 ml per g tissue) using a ground glass homogenizer. The homogenate was then centrifuged for 20 min at 1,000g, the supernatant aspirated and its pH adjusted to 7.5 using 1 M NaOH. This material was then assayed at multiple doses against unlabelled LHRH agonist; dilutions of standard and test material were made using 0.1 M acetic acid adjusted to pH 7.5 and containing 0.2% bovine serum albumin (fraction V, Sigma). In subsequent studies, an acid/ethanol extraction procedure was used, based on conventional techniques for the extraction of LHRH from the hypothalamus¹⁸. Thus, washed seminiferous tubules were homogenized in 0.1 M acetic acid (1 ml per g tissue) and the supernatant collected by centrifugation. The pellet was re-homogenized in the same volume of 0.1 M acetic acid and the resultant supernatant combined with the initial extract and lyophilized. The dried powder was then extracted with 0.1 M acetic acid in ethanol (1:40, v/v) at -20°C , using 0.5 ml per g original tissue. The extract was centrifuged for 10 min at 1,000g, the supernatant aspirated and evaporated to dryness in a stream of nitrogen at 45°C . The residue was dissolved in either 0.1 M acetic acid (pH 7.5) or 0.01 M phosphate-buffered saline (pH 7.5) at a concentration of 1 ml per 10 g original tissue. The pH of the extract was then adjusted to 7.5 using 1 M NaOH and the material stored at -20°C before assay. Representative displacement curves for three crude (○, △, ■) and two acid/ethanol (△, □) extracts are shown in relation to the LHRH agonist standard curve. The latter is a composite curve (mean $\pm$ s.d.) derived from 15 successive assays and illustrates its excellent reproducibility. Parallelism of standard and sample dose-response curves was tested using two-factor analysis of variance (with replication). Of a total of 9 crude and 12 acid/ethanol extracts assayed at 3 or more dilutions, only 5 samples gave dose-response curves which showed significant ($P < 0.05$ to $P < 0.01$) non-parallelism with the LHRH agonist standard; in all 5 instances, this deviation was apparent only at high concentrations of the extract which gave more than 75% suppression of binding (for example, see Fig. 3).

Fig. 2 *In vitro* receptor-binding activity and biological activity (inset) of acid/ethanol extracts of rat seminiferous tubules or macaque testis. Details of the extraction procedure for rat seminiferous tubules and the receptor assay method were as described in Fig. 1 legend. A single healthy, adult stump-tailed macaque of proven fertility was killed with an overdose of sodium pentobarbitone (Nembutal, May & Baker) and the testes immediately dissected out and kept on ice. After decapsulation the tissue was cut into ~1-g segments which were homogenized and extracted using acid/ethanol as described for rat seminiferous tubules; the final extract contained the equivalent of 10 g tissue per ml. The *in-vitro* biological activity of the extracts was determined by their ability to stimulate LH release from rat hemipituitaries⁹ using methods described elsewhere³⁰. One half of each donor hemipituitary was incubated in the presence of the extraction medium (pH 7.5) and the contralateral hemipituitary was incubated in the presence of 0.2 ml of either the extracts or LHRH agonist (10^{-6} M). LH release in the presence of the test materials has been expressed as a % of that released by the contralateral (control) hemipituitary. LH was determined by radioimmunoassay³¹ and results are the mean $\pm$ s.d. for three incubations.

Fig. 3 Displacement of the binding of ^{125}I -LHRH agonist or ^{125}I -HCG (inset) to dispersed Leydig cells by acid/ethanol extracts of either rat seminiferous tubules or Sertoli cell culture medium. The same preparation and concentration of dispersed Leydig cells was used for both receptor assays. The HCG-receptor assay was performed as described elsewhere²⁹, and HCG CR115 (13,600 IU per mg) was used as standard. The seminiferous tubule extract was prepared as described in Fig. 1 legend, except that the pH of the initial acid extract was adjusted to 7.5, and the resulting precipitate removed by centrifugation, before lyophilization. Cultures of Sertoli cells from 21-day old rats were prepared as described elsewhere³² and maintained in culture for either 1 (▲) or 6 (△) days; in the latter instance the culture medium (5 ml per flask) was replaced after 1 and 5 days. Each culture flask contained ~700 μg protein and Sertoli and Leydig cells formed >90% and <3%, respectively, as judged by morphology, histochemistry^{32,33} and LH-dependent steroid production. Culture medium was stored at -20°C before extraction. The medium from at least eight separate cultures was pooled and lyophilized after adjusting the pH to 7.5. The powder was then extracted in acid/ethanol (1 ml per 5 ml culture medium) as described for seminiferous tubules in Fig. 1 legend. The final extract contained the equivalent of 30 ml culture medium per ml.

curves parallel to the unlabelled LHRH agonist, whereas native LHRH showed <0.1% cross-reaction (Fig. 4). As there is evidence that LHRH-like molecules may be produced in other extra-hypothalamic tissues²¹, for example the ovary^{22,23}, the availability of an antibody which does not measure hypothalamic LHRH may have widespread applications.

Impairment of the secretory function of Sertoli cells, as for example in cryptorchidism^{24,25}, is associated with marked hypertrophy of the Leydig cells²⁶, and similar morphological changes have been observed locally within the testis around implants of anti-androgens³. These data have been interpreted as evidence that the Leydig cells may be under the inhibitory control of an androgen-dependent factor from the Sertoli cells³. Various findings suggest that the LHRH-like factor from the Sertoli cell, which we have described, may be this inhibitor. First, all the direct effects of injected LHRH agonists on Leydig cell function are inhibitory²¹, and it is particularly relevant that

Fig. 4 Cross-reactivity of acid/ethanol seminiferous tubule extracts in radioimmunoassays for LHRH agonist and LHRH (inset). The radioimmunoassay method described previously for LHRH³⁴ was used for both assays and separation of bound and free hormone was achieved using ice-cold ethanol. ¹²⁵I-labelled LHRH or LHRH agonist was used as tracer in their respective assays and all samples and standards were run in duplicate. Details of the LHRH antibody and its specificity have been described elsewhere³⁵; LHRH agonist showed <0.1% cross-reaction in this LHRH radioimmunoassay. The antibody used in the LHRH agonist radioimmunoassay was obtained as follows. Five rabbits were immunized with ((D-Ser-t-bu⁶, des-Gly-NH₂¹⁰) LHRH ethylamide) (LHRH agonist) conjugated to human serum albumin using carbodiimide, as described for LHRH³⁶. Only one of the antisera (R103) cross-reacted with the seminiferous tubule extracts and this was used to develop a radioimmunoassay. The antibody was used at a final concentration of 1:12,000 and at this concentration specifically bound 26.2±4.6% (mean±s.d., n=4) of the added ¹²⁵I-LHRH agonist; the detection limit of the assay (the mass of standard required to suppress binding by 10%) was 7.5±1.1 pg. Of the peptides tested, only fragments of the LHRH agonist showed major cross-reaction with the antibody. TRH, thyrotropin releasing hormone.

the stimulatory effects of FSH on Leydig cell function (Sertoli cell-mediated effects) are totally abolished by concomitant treatment with LHRH agonists¹⁴. Second, treatment of rats with HCG, which markedly raises their intra-testicular levels of testosterone²⁷, stimulates the secretion of an LHRH-like factor into the interstitial fluid that surrounds the Leydig cells⁹, and this coincides temporally with the onset of Leydig cell down-regulation²⁸. The fact that changes as drastic as those detailed above can result from alteration of Leydig cell exposure to LHRH-like factors, suggests that this Sertoli cell hormone may have a central regulatory role in the maintenance of normal testicular function and fertility.

We thank Dr J. Sandow for helpful discussions and advice, Mrs M. Swaney for technical assistance, Drs J. Sandow and S. Dombey (Hoechst) for supplies of peptide hormones, and the National Pituitary Agency, NIAMDD, USA, for purified HCG and materials for rat LH radioimmunoassay.

The delayed therapeutic effects of antidepressants (usually between 10 and 14 days)^{1,2} and of the tricyclic antidepressants in particular, are believed (on the basis of animal experiments³⁻⁸) to lie in a progressive decrease of the sensitivity of cortical β -adrenergic receptors. This is thought to be due to an increase in the synaptic concentration of noradrenaline, in turn accomplished by a decrease in the sensitivity of the presynaptic α_2 receptors which normally regulate noradrenaline secretion by a negative feedback mechanism. This model suggests that the desensitization of postsynaptic β -receptors by antidepressants should be accelerated by the inhibition of the presynaptic α_2 -adrenergic system, and we have indeed observed such an effect in preliminary studies with desipramine and phenoxybenzamine (PBZ) combined⁹. We now show that the administration of either tricyclic or monoamine oxidase inhibitor antidepressants in combination with PBZ, an irreversible α -adrenergic blocker^{9,10}, accelerates and intensifies the desensitization of β -adrenergic receptors. Our observations may have therapeutic implications.

Male Sprague-Dawley rats (125–150 g) were injected intraperitoneally (i.p.) with antidepressant, PBZ (7.5 mg per kg), combined antidepressant and PBZ (7.5 mg per kg), or vehicle, once daily. Rats were killed 24 h after the last dose of drug or vehicle. The cerebral cortices were dissected, weighed and homogenized using a Brinkmann polytron (setting 5, 50 s). Cortical membranes were sedimented by centrifugation (20,000g, 20 min at 4 °C), washed twice (20 vol w/v) and resuspended in 20 volumes of ice-cold 50 mM Tris-HCl buffer (pH 8.0). Aliquots of tissue equivalent to ~400–500 µg of protein were assayed for β -adrenergic receptors using ^3H -dihydroalprenolol (^3H -DHA) as described elsewhere¹¹. The binding of ^3H -DHA (0.1–3.0 nM, specific activity 32 Ci mmol⁻¹, NEN) was carried out at 23 °C for 20 min in a total incubation volume of 0.5 ml of 50 mM Tris-HCl buffer (pH 8.0). Assays were run in quintuplicate with two tubes containing 10 µM *dl*-propranolol to assess nonspecific binding. Incubations were terminated by rapid filtration at reduced pressure through Whatman GF/B glass fibre filters. Filters were washed five times with 5 ml of ice-cold buffer, dried, transferred to scintillation vials containing 10 ml of Aquasol (NEN) and counted in a liquid scintillation counter. Specific binding, defined as the total binding minus nonspecific binding, was ~85%.

As in previous reports, acute treatment with desipramine (DMI, 7.5 mg per kg, i.p.) a prototype tricyclic antidepressant for 1, 2 or 3 days had no significant effect on the binding of ^3H -DHA to cerebral cortical membranes compared with vehicle-treated controls. Continuous administration of DMI for 6 or 12 days decreased ^3H -DHA binding by $24 \pm 4\%$ ($P < 0.05$) and $22 \pm 6\%$ ($P < 0.05$, Fig. 1), respectively. In contrast to DMI treatment alone, only one dose of combined DMI+PBZ significantly decreased ^3H -DHA binding ($14 \pm 2\%$, $P < 0.01$) compared with vehicle-treated controls (Fig. 1). Combined administration of DMI+PBZ for 2 and 3 days further reduced cerebral cortical β -adrenergic receptor density to that observed during chronic treatment with DMI alone (Fig. 1 and unpublished observations). Furthermore, during chronic administration of DMI+PBZ there was a significantly greater reduction in the density of cerebral cortical β -adrenergic receptors than that found during DMI administration alone (Fig. 1). For example, after 12 days of treatment with DMI and PBZ, specific ^3H -DHA binding was reduced by $34 \pm 3\%$ compared with $22 \pm 6\%$ with DMI alone ($P < 0.05$). All changes in ^3H -DHA binding after treatment with DMI or combined with DMI+PBZ, as determined by Scatchard analysis (Fig. 1), were due to a decrease in the density of β -adrenergic receptors and not a change in affinity (apparent K_d). These results indicate that combined DMI+PBZ administration desensitizes cortical β -receptors both more rapidly and to a greater extent than treatment with DMI alone.

Although there was a slight trend toward decreasing ^3H -DHA binding during chronic treatment with PBZ (7.5 mg per kg, i.p., data not shown) there were no statistically significant changes in ^3H -DHA binding after 1, 2, 3, 6, or 12 days of PBZ administration. The addition of PBZ (1 µM), DMI (1 µM) or combined DMI+PBZ (1 µM each) to cerebral cortical membranes *in vitro* did not significantly alter ^3H -DHA binding. As these concentrations are equivalent or even higher than those observed in washed membrane preparations, these results suggest that neither DMI nor PBZ directly interfere with ^3H -DHA binding.

To determine whether the synergistic actions of combined DMI+PBZ administration on cerebral cortical β -receptor desensitization were due to increased brain levels of desipramine, ^3H -DMI (7.5 mg per kg, i.p., 3.5 mCi mmol⁻¹, NEN) was injected into rats either alone or in combination with PBZ (7.5 mg per kg). Rats were killed 6 h later and the cerebral cortices dissected, weighed and homogenized in 20 volumes of alkaline ethanol. The radioactivity in an aliquot of the brain extract was determined in a liquid scintillation counter as described above. More than 90% of the radioactivity was extracted using this procedure. The levels of DMI and its metabolites were found to be 1.26 ± 0.09 ($n = 9$) and 1.14 ± 0.06 ($n = 9$) nmol per mg wet weight for rats treated with DMI alone or DMI in combination with PBZ, respectively. TLC of brain extracts from both groups of animals showed that 82% of radioactivity migrated with an R_F value identical to that of authentic DMI. These findings indicate that the effects of combined DMI+PBZ administration on cortical β -receptor desensitization are not due to changes in DMI metabolism.

To determine whether the rapid desensitization of cortical β -receptors found during combined PBZ+DMI (a prototype tricyclic antidepressant) treatment was true for other types of antidepressant drug, experiments were done using tranlylcypromine and pargyline, two chemically different monoamine oxidase inhibitors. Treatment with tranlylcypromine (10 mg per kg) alone for 1 or 2 days did not change ^3H -DHA binding. In contrast, combined tranlylcypromine (10 mg per kg)+PBZ (7.5 mg per kg) treatment reduced ^3H -DHA binding by $19 \pm 2\%$ ($P < 0.01$, Fig. 2) after 1 day of treatment and $19 \pm 1\%$ ($P < 0.01$) after 2 days of treatment. Six days of tranlylcypromine alone did decrease ^3H -DHA binding by $19 \pm 3\%$ ($P < 0.05$) compared with a decrease of $23 \pm 2\%$ ($P < 0.01$) with combined tranlylcypromine+PBZ treatment for 6 days. Pargyline (25 mg per kg), like tranlylcypromine, also had no significant affect on ^3H -DHA binding after 1 or 2 days of administration whereas after 6 days ^3H -DHA binding was reduced by $18 \pm 2\%$ ($P < 0.01$, Fig. 2). Combined pargyline (25 mg per kg)+PBZ (7.5 mg per kg) administration reduced ^3H -DHA binding by 5% after 1 day, 19% ($P < 0.01$) after 2 days and 23% ($P < 0.01$, Fig. 2)

Fig. 1 *a*, Scatchard analysis of ^3H -DHA binding to cerebral cortical membranes from rats treated with vehicle, DMI (7.5 mg per kg), or DMI (7.5 mg per kg)+PBZ (7.5 mg per kg) once daily for 2 days. The inset shows the saturation isotherm of ^3H -DHA binding as a function of increasing concentrations of ^3H -DHA. Bound/free, ratio of specifically bound to free ^3H -DHA. *b*, Effects of DMI (7.5 mg per kg) alone (open bars) or combined DMI (7.5 mg per kg)+PBZ (7.5 mg per kg) (hatched bars) on the development of cerebral cortical β -adrenergic receptor desensitization. Animals were administered vehicle or drugs i.p. once daily, and the number of β -adrenergic receptors determined 24 h after the last dose as described in the text. Values are the $\bar{x} \pm \text{s.e.m.}$ of the per cent change in the density (B_{max} as estimated by Scatchard analysis) of ^3H -DHA binding sites in cerebral cortical membranes from drug-treated animals compared with vehicle-treated controls. Control values were ~0.16 pmol ^3H -DHA bound per mg protein. Treatment with PBZ (7.5 mg per kg) alone had no significant effect on binding. Each experiment consisted of groups of six animals and was repeated twice. * $P < 0.01$; † $P < 0.05$; ‡ $P < 0.001$ (Student's *t*-test).

Fig. 2 *a*, Effects of tranylcypromine (10 mg per kg) alone (open bars) or combined tranylcypromine (10 mg per kg)+PBZ (7.5 mg per kg) (hatched bars) on the development of cerebral cortical β -receptor desensitization. *b*, Effects of pargyline (25 mg per kg) alone (open bars) or combined pargyline (25 mg per kg)+PBZ (7.5 mg per kg) (hatched bars) on the development of cerebral cortical β -receptor desensitization. Values are the $\bar{x} \pm s.e.m.$ of the per cent change in the density (B_{max} as estimated by Scatchard analysis) of ^3H -DHA binding sites in cerebral cortical membranes from drug-treated animals compared with vehicle-treated controls. Each experiment consisted of groups of six animals and was repeated twice. * $P < 0.01$; † $P < 0.05$ (Student's *t*-test).

after 6. In both these studies treatment with vehicle or PBZ (7.5 mg per kg) alone had no significant effect on ^3H -DHA binding. Thus, combined treatment of antidepressant monoamine oxidase inhibitors and PBZ can rapidly decrease β -adrenergic receptor density.

As the desensitization of cortical β -receptors during chronic tricyclic antidepressant treatment can be prevented by destruction of ascending noradrenergic neurones from locus coeruleus⁷, chronic treatment with tricyclic antidepressants probably increases the stimulation of β -receptors by increasing the synaptic concentration of noradrenaline. However, acute antidepressant administration decreases the adrenergic activity of locus coeruleus neurones apparently by increasing presynaptic α_2 -receptor inhibition¹². Recent studies in both the peripheral and central nervous systems have demonstrated that chronic antidepressant administration reduces this presynaptic α_2 -receptor inhibition^{8,13}, resulting in enhanced noradrenaline release which would be expected to desensitize postsynaptic cerebral cortical β -receptors. Thus, the increase in presynaptic α_2 -receptor inhibition during acute antidepressant treatment is opposite to the chronic and apparently therapeutically relevant effects of these agents.

In our experiments administration of PBZ probably blocks presynaptic α_2 -receptor feedback inhibition, allowing DMI, an inhibitor of noradrenaline uptake, to increase acutely the synaptic noradrenaline concentration and thereby rapidly desensitize cortical β -receptors. Consistent with this interpretation is the finding that yohimbine, another presynaptic α_2 blocker, in combination with DMI (5 mg per kg) decreased cortical β -receptor density in 4 days whereas DMI alone produced no change¹⁴.

The synergistic actions of tricyclic and monoamine oxidase inhibitor antidepressants with PBZ, an α -adrenergic antagonist, are probably due to increases in the synaptic concentrations of

noradrenaline. Rapid decreases in β -receptor binding sites have been shown to occur *in vitro* during exposure of cerebral cortical slices to β -adrenergic agonists¹⁵. The rapid decrease in ^3H -DHA binding reported here after DMI + PBZ treatment indicates that cerebral cortical β -adrenergic receptors can also be rapidly desensitized *in vivo*. The rapid desensitization of cerebral cortical β -receptors during administration of antidepressants and α -adrenergic antagonists has several important implications. As postsynaptic cortical β -receptors are thought to be directly involved in the therapeutic actions of most, if not all, antidepressants³, combined treatment with antidepressant and a presynaptic α_2 -receptor antagonist may provide a therapy with rapid onset of action. In addition, the greater reduction of β -receptor density produced by combined antidepressant + PBZ, compared with antidepressant alone, indicates that administration of an α -adrenergic antagonist may enhance the effects of antidepressants in previously nonresponsive patients. Finally, the decrease in β -receptor density after only one dose of combined antidepressant + PBZ treatment could serve as a rapid screening procedure for new antidepressant drugs.

We thank the Merrell-National Laboratories for desipramine and Smith Kline and French Laboratories for PBZ. F.T.C. thanks J. Axelrod for providing laboratory facilities and constructive comments.

Isolation of a biologically active macrophage receptor for the third component of complement

Robert J. Schneider*†, Anthony Kulczycki Jr*‡, S. K. Law§ & John P. Atkinson*†

* Howard Hughes Medical Institute Laboratories and the Department of Medicine, † Division of Rheumatology and ‡ Division of Allergy and Immunology, Washington University School of Medicine, St Louis, Missouri 63110, USA
§ Department of Genetics, Washington University School of Medicine, St Louis, Missouri 63110, USA

C3b, the major cleavage fragment of the third component of complement (C3), has been demonstrated to bind to a specific receptor on various mammalian cells¹. Tissue-bound C3b receptors have also been demonstrated, most conclusively in renal glomeruli². On interaction with C3b, C3b receptors are thought to initiate cellular functions such as phagocytosis and to determine the fate of complement-fixing soluble and particulate immune complexes. We report here the isolation by affinity chromatography of a macrophage glycoprotein with an apparent molecular weight (MW) of ~64,000 that has properties expected of the C3b receptor. It is a cell-surface macromolecule (labelled with ¹²⁵I and lactoperoxidase) which, in its isolated state, retains the ability to bind both C3 and C3b.

Human C3 was purified by the method of Tack and Prahl³, and was demonstrated to be haemolytically active³ and to retain its ¹⁴C-methylamine-binding capacity⁴. Three separate C3 preparations were used in the experiments; in most of them a preparation with >95% methylamine-binding capacity was used. C3b and C3d were prepared from C3 by trypsin digestion followed by gel filtration on Sephadex G-100 (ref. 5), and C3d was further purified by ion-exchange chromatography on DEAE-Sephacel⁴. The purities of the C3, C3b and C3d preparations were estimated by polyacrylamide gel electrophoresis (PAGE)⁶ to be at least 95%. C3 and C3b were coupled to Sepharose beads with cyanogen bromide with an efficiency of 57–86% and prepared for use as immunoadsorbents as described previously^{7–9}.

Elicited rabbit alveolar macrophages were collected, radiolabelled using modifications of the lactoperoxidase method¹⁰ and solubilized at 4 °C for 5 min in borate-buffered saline (BBS) containing 1% NP40 and 2 mM phenylmethylsulphonyl fluoride (PMSF)⁷. The 30,000g supernatant⁷ of the solubilized fraction of $\sim 2 \times 10^8$ cells was incubated with 0.4 ml of C3b-Sepharose for 1 h at room temperature. This mixture was then centrifuged at 300g for 5 min and the immunoadsorbent beads resuspended in 6.0 ml of BBS containing 1% NP40 and 2 mM PMSF, and washed twice in 0.7 × 4-cm glass columns with 4.0 ml of BBS containing 1%

NP40. C3b-binding molecules were subsequently eluted at room temperature with four successive 1.0-ml aliquots of 0.5 M acetic acid containing 1% NP40 into tubes with 0.375 ml of 2 M Tris, pH 8.6, containing 1% NP40 (to achieve complete, rapid neutralization). Using this procedure, we eluted 0.01–0.15% of the applied radioactivity from the immunoadsorbent columns.

When the acid eluate was analysed by SDS PAGE in rod gels in reducing conditions (1% β -mercaptoethanol), a single protein peak of MW $\sim 64,000 \pm 3,500$ (mean $\pm$ s.d. of 21 gels) was demonstrated (Fig. 1a). Purity, estimated by either determining the area under the curves or by cutting out and weighing the individual peaks, was routinely >90%. A similar peak was purified from the solubilized radiolabelled cells using C3b immunoadsorbent beads that had been prepared by the incubation of Sepharose with normal human serum¹¹, although other contaminating materials were also present (data not shown). No peak was observed if purification was attempted using beads prepared from heat-inactivated serum or using bovine serum albumin (BSA)-Sepharose. To exclude the possibility that trace contamination by IgG in our C3b preparation might allow co-purification of Fc γ receptor⁷, we preincubated the solubilized preparation with IgG-Sepharose. In three such experiments we recovered 92.5, 97.3 and 108% as much C3b receptor from the aliquot preincubated with IgG-Sepharose as from the aliquot not preincubated but isolated directly using only C3b-

The ligand-binding activity of the putative receptor macromolecule was determined in a manner analogous to that described for the Fc γ receptor^{7,13}. Briefly, aliquots of the acid eluates were added to plastic tubes containing 0.10 ml immunoadsorbent. Inhibitor proteins were preincubated with the isolated receptor for 30 min at room temperature. Mixtures of immunoadsorbents and receptor preparations were incubated for 90 min at room temperature. Washed beads, supernatants and washes of triplicate samples were counted in a γ counter and the per cent rebinding of labelled receptor determined. Data presented are from representative experiments. The amounts of protein coupled to immunoadsorbents (mg protein per ml beads) were: C3b, 2.4–11.6 mg ml⁻¹; C3, 1.7–11.3 mg ml⁻¹; rabbit IgG, 6.8–15.7 mg ml⁻¹; and BSA, 4.5 mg ml⁻¹. For all rebinding studies, the amount of C3 or C3b present was in excess of that required to bind all of the available receptor.

* Represents rebinding of Fc γ receptor, which demonstrates the expected MW $\sim 35,000$ –55,000 (ref. 7) in SDS-polyacrylamide gels.

† The supernatant from the IgG-Sepharose column shown in the first part of expt 2 was adsorbed on C3b-Sepharose. The ligand-binding activity of the acid eluate from this second column is shown here.

‡ The supernatant from the C3b-Sepharose column shown in the first part of expt 2 was adsorbed on IgG-Sepharose. The ligand-binding activity of the acid eluate from this second column is shown here.

§ In these dose-dependent inhibition studies, ovalbumin (OVAL) was added to achieve a total protein content of 3.0 mg.

Fig. 1 SDS-PAGE in rod gels of C3b receptor. Representative results of five different types of experiment are shown. Samples were eluted with acid as described in the text and the eluates were prepared for electrophoresis using the Tris-glycine buffer system²¹ with 0.1% SDS and 9.0% acrylamide separating gels and 3.0% acrylamide stacking gels, using methods described previously⁷. Buffers for sample preparation contained 1% β -mercaptoethanol. The positions of six standard proteins are indicated by their molecular weights. Gels were sliced with an electric gel slicer, and radioactivity in 2-mm gel slices counted. *a*, Receptor from C3b-Sepharose. *b*, The ¹²⁵I-labelled, solubilized fraction was first incubated with IgG-Sepharose (to deplete Fc γ receptor from the preparation). This supernatant was subsequently incubated with C3b-Sepharose and the receptor was eluted and analysed as above. (The difference in counts between *a* and *b* reflects only the fact that one-fifth as many counts were loaded in the latter gel. As noted in the text, preincubation of the solubilized preparation with an IgG immunoadsorbent did not alter the quantity of C3b receptor obtained.) *c*, Receptor from C3-Sepharose. *d*, After collection by usual methods, the macrophages were resuspended in Hank's balanced salt solution (HBSS) at a concentration of 1.3×10^6 cells ml⁻¹. Cell suspension (8 ml) was placed on each of 45 100-mm plastic Petri dishes and incubated for 30 min at 37°C in a 5% CO₂ incubator. The nonadherent cells were removed by washing once with 5 ml of HBSS. The plated cells were solubilized with 4 ml of BBS containing 1% NP40 and 2 mM PMSF, and freed from the plates with a rubber policeman. The plates were serially washed with an additional 4 ml of the BBS containing 1% NP40 and 2 mM PMSF⁷. The solubilized preparation thus obtained was centrifuged at 30,000g for 20 min at 4°C and the C3b receptor isolated by affinity chromatography as above. A small peak at ~25,000 MW is present in this preparation (and also in the simultaneously prepared material obtained from the unplated cell population—not shown). Similar macromolecules were observed in 2 of the other 15 receptor preparations. *e*, Rabbit alveolar macrophages were collected and washed as above using sterile buffers and aseptic technique. Cells were subsequently suspended at 10^6 cells ml⁻¹ in sterile spinner flasks in minimal essential medium containing 10% fetal calf serum, 2 mM L-glutamine, 0.01% D-glucose, 1 mM pyruvate and 1:100 antibiotic/antimycotic mixture. Deoxyribonuclease I (10 μ g ml⁻¹) and ¹⁴C-glucosamine (1 mCi) were added to the medium. After 18–20 h culture at 37°C, the cells were collected by centrifugation and washed twice in 0.01 M phosphate, 0.15 M NaCl, pH 7.4 (phosphate-buffered saline, PBS) containing 1% BSA followed by a final wash in PBS. Cells were solubilized at 10^8 cells ml⁻¹ in PBS containing 1% NP40 and 2 mM PMSF⁷. The suspension was then centrifuged at 30,000g for 20 min at 4°C, and the supernatant applied to a C3b-Sepharose affinity column for 60 min at room temperature. The column was washed and eluted as described in the text to obtain receptor from intrinsically labelled cells.

Fig. 2 SDS-PAGE in slab gels was performed according to the method of Laemmli⁶ using 0.1% SDS gels. Preparation of a linear gradient of polyacrylamide from 6 to 18% and a 3% stacking gel, gel fixation, staining, destaining and autoradiography have been described elsewhere¹³. Samples were prepared as described in Fig. 1 legend. *a*, Acid eluate from C3-Sepharose. *b*, A portion of the acid eluate in *a* was adsorbed on a new C3-Sepharose column. The rebound material was eluted with 6 M guanidine containing 1% NP40 and the sample prepared for analysis as above.

Sepharose. Macromolecules of identical MW were isolated from C3b-Sepharose and from C3-Sepharose (Fig. 1c); a similar protein was also obtained from an immunoadsorbent prepared by the coupling of C3 to Affi-Gel 10 (BioRad). The polyacrylamide gel electrophoretic mobility and pattern of the putative C3b receptor were not altered by: (1) addition of protease inhibitors (diisopropylfluorophosphate 10 mM, iodoacetamide 20 mM, or soybean trypsin inhibitor 2 mg ml⁻¹) in the solubilization buffer; (2) incubation temperature (4, 22 or 37°C) for affinity chromatography step; (3) omission of β -mercaptoethanol from the sample buffer; or (4) presence of Ca²⁺ and Mg²⁺ during solubilization and affinity chromatography. As alveolar cells contained an average of ~80% macrophages, adherent cells containing >95% macrophages⁷ were used in three experiments to obtain C3b receptor, and an identical macromolecule was isolated (Fig. 1d). Biosynthetic labelling with ¹⁴C-glucosamine demonstrated that, like the Fc ϵ ^{9,12} and Fc γ ⁷ receptors, the C3b receptor is a glycoprotein (Fig. 1e).

The ligand-binding activity of the affinity chromatography-purified material (always lower than the purity estimated by SDS-PAGE) was determined by the ability of the acid eluates to rebinding to a new immunoadsorbent column. In 12 such rebinding experiments the specific activity (rebinding to C3b-Sepharose minus rebinding to IgG-Sepharose or BSA-Sepharose) ranged from 22.9 to 62.3% (representative experiments are presented in Table 1). The per cent of rebinding was characteristic for each receptor preparation. The variability between preparations did not reflect differences in purity but rather partial denaturation during the obligatory acid elution procedure. The ligand-binding activity of the isolated receptor was independent of Ca²⁺ and Mg²⁺; it was stable for several hours at room temperature and at least several weeks at -70°C. The receptor rebound to both C3b-Sepharose and C3-Sepharose (Table 1, expt 1). Preincubation of the solubilized preparation with IgG-Sepharose, which removes Fc γ receptor⁷, did not alter the specific activity

of the C3b-binding protein eluted subsequently from a C3b-Sepharose column (Table 1, expt 2).

Two lines of evidence indicate that the ability of the isolated receptor to bind to both C3 and C3b was not due to conversion of C3 to either C3b or a C3b-like molecule during coupling to activated Sepharose. First, an alternative coupling procedure using Affi-Gel 10 allowed isolation of a similar macromolecule (see above). Second, both soluble C3 and soluble C3b were effective inhibitors of rebinding (Table 1, expt 3), although C3b was more effective in dose-dependent assays (Table 1, expt 4 is representative of three separate experiments). Soluble IgG, C3d and ovalbumin did not inhibit ligand-binding activity.

Aliquots of the acid eluates from the initial C3-Sepharose column were analysed in polyacrylamide gradient slab gels (Fig. 2a). Part of this material was rebound to a second C3-Sepharose column and then eluted with 6 M guanidine containing 1% NP40 (ref. 7), dialysed and analysed in gels (Fig. 2b). Electrophoretic patterns of both eluates demonstrated similar broad bands in the 58,000–68,000 MW region.

Like receptors for Fc γ ^{7,13} and Fc ϵ ^{9,12,14} previously isolated in these laboratories, the C3b-binding protein migrates as a broad band on polyacrylamide gels and retains specific ligand-binding activity. The molecular weight of the C3b receptor is higher than that of the Fc γ receptor isolated from rabbit alveolar macrophages, the latter having a MW of ~35,000–55,000 (ref. 7 and Table 1,*). Specific antibodies against analogously isolated Fc ϵ -binding molecules have been demonstrated to induce mast cell degranulation *in vitro*^{15,16}, providing definitive evidence that such binding molecules correspond to the biologically important Fc ϵ receptor. Similar evidence identifying Fc γ - or C3b-binding proteins conclusively as receptors has not yet been obtained. It now seems, however, that at least three important receptor molecules involved in immune responses are glycoproteins with apparent MWs in the 35,000–65,000 range and they can be isolated retaining ligand-binding activity in a highly purified state.

Although C3b was a more effective inhibitor in dose-dependent inhibition experiments than C3, both C3 and C3b bound to the putative complement receptor isolated from rabbit macrophages. Solubilization could possibly affect the observed specificity of the receptor as previously discussed^{12,14}. That C3 does bind directly to intact cells has been documented previously for lymphocytes¹⁷, but has not been evaluated for macrophages. Based on these data there may be a parallel between the IgG–Fc γ receptor interaction and the interaction of C3 and C3b with their receptor. Although both C3 and IgG can bind to their respective receptors, they exhibit a higher net affinity of binding on modification: by fixation to antigen allowing multi-point attachment in the case of IgG, or by cleavage and removal of the C3a fragment in the case of C3. In addition, receptor-bearing effector cells may interact more efficiently with membrane-bound C3b molecules clustered about an antigenic site than C3 molecules in solution.

Previous attempts to purify the C3b receptor from solubilized cells have been unsuccessful^{11,18}. Recently, using affinity chromatography with C3-Sepharose, Fearon¹⁹ isolated a 205,000-MW protein from human erythrocytes which has been implicated as the C3b receptor²⁰, although ligand-binding activity of the purified material was not reported. Its relationship to the complement-binding macrophage glycoprotein described here remains to be defined.

We acknowledge the technical assistance of V. Krause and thank Drs C. Hammer and M. Frank for providing purified C3 for use in preliminary experiments.

Cyclosporin A blocks receptors for HLA-DR antigens on T cells

Ronald Palacios* & Göran Möller

Department of Immunobiology, Karolinska Institute, Wallenberg Laboratory, Lilla Frescati, S-104 05, Stockholm, Sweden

Recent studies have shown that cyclosporin A, an undecapeptide extracted from two species of fungi (*Cylindrocarpum lucidum* and *Tricoderma polysporum*), has potent immunosuppressive effects with low myelocytotoxicity¹. In different experimental systems in both animals and humans, cyclosporin A administration decreased antibody production to T cell-dependent antigens, prolonged survival of skin, kidney and heart allografts^{1–3}, inhibited cytotoxic activity generated in the allogeneic mixed lymphocyte reaction⁴ and abrogated suppressor T-cell activity induced by concanavalin A (ref. 5). However, the mode of action of cyclosporin A and its role in establishing tolerance remains unclear. Continuous proliferation of T cells after stimulation with antigens or mitogens is maintained by growth factors, released by lectin- or antigen-activated T cells^{5,6}. One of these factors, interleukin 2 (IL-2), supports growth of activated but not of resting T cells^{5–6}, so that, to achieve a proliferative response a cell population must be 'activated' both to produce IL-2 and to become responsive to it. In the autologous mixed lymphocyte reaction (AMLR), purified human T lymphocytes proliferate when co-cultured with autologous B cells and/or macrophages^{7,8}. Recently, we found that antibodies against either the heavy non-polymorphic chain or the light polymorphic chain of HLA-DR antigens of the stimulator cells, prevented T cells from acquiring responsiveness to IL-2, inhibited the production of the growth factor and abrogated the T-cell proliferative response in AMLR and hapten-labelled autologous cell systems^{9,10}. These results suggested that the HLA-DR antigens rendered resting T cells sensitive to IL-2 and participated actively in the production of the growth factor. We have now studied the effect of cyclosporin A on the AMLR response, and found that the drug inhibited the proliferative response by blocking the receptors for HLA-DR antigens on T cells.

The addition of as little as 1 $\mu\text{g ml}^{-1}$ cyclosporin A to the AMLR cultures strongly inhibited the proliferative response when compared with control cultures. This inhibition occurred very early in the process of activation of the responding cells, for it was not seen if the drug was added 72 h after the initiation of the cultures (Fig. 1). Pretreatment of the T cells with 1 $\mu\text{g ml}^{-1}$ or more cyclosporin A abrogated proliferation in the AMLR, whereas treatment of the stimulator cells with up to 5 $\mu\text{g ml}^{-1}$ had no effect on the AMLR response. This indicates that cyclosporin A exerts its inhibitory effects by acting on the responding T cells rather than on the non-T stimulator cells, in

* To whom all correspondence should be sent.

agreement with previous studies which postulated a selective activity of cyclosporin A on T cells^{2,4}.

To define the mechanism by which cyclosporin A inhibits the AMLR response, we studied the sensitivity of the responding T cells to IL-2 in the presence or absence of the drug and its effect on the synthesis of IL-2 in the AMLR. The results show that T cells from AMLR cultures containing cyclosporin A did not respond to IL-2 stimulation, whereas T cells from cultures where no drug was added proliferated under the stimulus of IL-2 (Table 1). When previously activated T cells (by AMLR or by phytohaemagglutinin, PHA) were stimulated with different concentrations of IL-2 in the presence or absence of cyclosporin A inhibition did not occur, indicating that once T cells have responded to IL-2, they are no longer sensitive to the inhibitory effects of cyclosporin A (data not shown). These results, together with our previous findings that cyclosporin A-treated T cells are unable to absorb IL-2 whereas activated T cells are able to do so⁵, support the notion that the drug inhibits expression of IL-2 receptors on T cells^{5,11}. The production of IL-2 in the AMLR was also inhibited by the addition of cyclosporin A to the cultures (Table 2), suggesting a second mechanism by which this drug could inhibit T-cell activation in the AMLR.

It seems unlikely that cyclosporin A exerts its inhibitory effects by nonspecific toxic or lytic effects, for at the doses used in this study ($1-5 \mu\text{g ml}^{-1}$) the viability of the cells as determined by Trypan blue exclusion from AMLR cultures in the presence or absence of cyclosporin A were similar at the end of the culture period. Furthermore, the experiments carried out to determine

Table 1 Response to IL-2 of T cells from AMLR cultures performed in the presence or absence of cyclosporin A

Cells	Dilutions of IL-2		
	1:2	1:4	1:8
T cells cultured alone	$1.1 \pm 0.1^*$	1.0 ± 0.3	0.9 ± 0.1
T AMLR	9.1 ± 1.3	6.5 ± 0.2	4.1 ± 0.5
T AMLR + $1 \mu\text{g ml}^{-1}$ cyclosporin A	1.3 ± 0.4	0.8 ± 0.4	0.8 ± 0.2
T AMLR + $3 \mu\text{g ml}^{-1}$ cyclosporin A	1.0 ± 0.3	0.7 ± 0.2	0.9 ± 0.1

Cell separation: Peripheral blood mononuclear cells (MNC) from healthy adult volunteers were obtained as previously described^{5,7}. T and non-T cells were isolated by rosetting MNC with sheep red blood cells (SRBC) as described elsewhere⁷. After osmotic lysis of the erythrocytes, the lymphocytes were washed and resuspended in RPMI 1640 medium (Gibco) supplemented with 10% of heat-inactivated human AB serum, $20 \mu\text{g ml}^{-1}$ of gentamicin, glutamine and 1% of HEPES buffer solution (Gibco) which will be referred to as complete culture medium (CCM). Autologous mixed lymphocyte reaction cultures: AMLR cultures were performed as previously described⁷. Briefly, 10^5 T cells were cultured with 10^5 irradiated autologous non-T cells in round-bottom microtitre plates (Nunc) Delta, Nunc). The secondary AMLR cultures were established by co-culturing 10^5 T cells from each primary AMLR culture with 10^5 of the following irradiated ($2,500 \text{ rad}$) autologous stimulator cells: non-T cells, T cells activated by PHA for 8 days (T-PHA), T cells from AMLR cultures performed in the presence or absence of cyclosporin A and peripheral blood MNC stimulated with PHA for 4 days (MNC-PHA). Cultures in triplicate were incubated at 37°C in a humidified atmosphere of 5% CO_2 in air. $0.5 \mu\text{Ci}$ of ^3H -thymidine (Radiochemical Centre) was added to each well 12 h before the end of a 7-day culture for primary AMLR cultures and a 3-day culture period for secondary cultures. ^3H -thymidine uptake of the cultures was determined as previously described^{6,7}. Cyclosporin A was tested for its ability to inhibit the proliferative response in AMLR by adding different doses of the drug ($1-5 \mu\text{g ml}^{-1}$) to the cultures either at the initiation of or at different intervals during culture. In no instance was the concentration of ethanol (in which cyclosporin A was dissolved) greater than 0.25% whether in the cultures containing this drug or in medium (control). IL-2 obtained from PHA-stimulated MNC was added to 10^2 T cells of the following groups: T cells cultured but not stimulated, T AMLR = T cells from AMLR cultures, T AMLR + $1 \mu\text{g}$ or $3 \mu\text{g}$ cyclosporin A = T cells from AMLR cultures treated with cyclosporin A. Proliferation was determined by the incorporation of ^3H -thymidine during the last 12 h of the 2-day culture period.

* c.p.m. $\times 10^{-3}$, mean $\pm$ s.d. of seven independent experiments.

Table 2 Effect of cyclosporin A on the synthesis of IL-2 in the AMLR

Supernatant source	Dilutions of IL-2		
	1:2	1:4	1:8
T cells culture alone	$1.1 \pm 0.2^*$	1.0 ± 0.1	1.0 ± 0.2
AMLR	15.2 ± 2.4	10.6 ± 1.5	8.4 ± 0.9
AMLR + $1 \mu\text{g ml}^{-1}$ cyclosporin A	2.9 ± 0.7	1.9 ± 0.2	1.8 ± 0.4
AMLR + $3 \mu\text{g ml}^{-1}$ cyclosporin A	1.6 ± 0.5	1.8 ± 0.3	1.5 ± 0.2

IL-2 production. IL-2 was obtained from AMLR cultures as previously described⁵. Briefly, 3×10^6 T cells and 3×10^6 irradiated autologous non-T cells suspended in 1 ml of CCM in the presence or absence of 1 and $3 \mu\text{g ml}^{-1}$ of cyclosporin A were incubated in 17×100 -mm round-bottom plastic tubes (Falcon) at 37°C for 48 h. After the first 24 h of culture, the cells were washed three times in CCM, resuspended in CCM in the absence of cyclosporin A and incubated for the last 24 h of culture. After this, the tubes were centrifuged at 2,000 r.p.m. for 15 min, and the supernatants collected, filtered through $0.45 \mu\text{m}$ and stored at -20°C until used. The experiments performed to find out whether cyclosporin A inhibits the proliferative response of previously activated T cells to IL-2 stimulation were established as follows: 10^4 T cells, activated in AMLR or by PHA and maintained in culture with conditioned media containing IL-2 for at least 3 weeks, were placed in flat-bottom microtitre plates. Three different dilutions of AMLR supernatants with proved IL-2 activity or IL-2 obtained after 48 h of PHA stimulation of peripheral blood MNC as described by Bonnard *et al.*¹⁶ was added with cyclosporin A (1 and $3 \mu\text{g ml}^{-1}$) or medium to each well. Cultures in triplicate were incubated at 37°C for 48 h and proliferation during the last 12 h was determined by the incorporation of ^3H -thymidine as described elsewhere^{3,7}. Supernatants from the following cultures: T cells cultured but not stimulated, AMLR = T cells and irradiated autologous non-T cells, AMLR + $1 \mu\text{g}$ or $3 \mu\text{g ml}^{-1}$ cyclosporin A = T cells co-cultured with irradiated autologous non-T cells in the presence of cyclosporin A, were placed at three different final dilutions in each well of microtitre plates containing 10^4 T cells activated by PHA and maintained in culture with conditioned media plus IL-2 for 3 weeks. After 48 h of incubation, incorporation of ^3H -thymidine was determined (see Table 1 legend).

* c.p.m. $\times 10^{-3}$, mean $\pm$ s.d. of seven separate experiments.

the effects of this drug on the response to IL-2 stimulation of previously activated T cells revealed that cyclosporin A did not inhibit the proliferation of these cells after IL-2 stimulation. Moreover, the observation (Fig. 1) that T-cell proliferation was not inhibited when cyclosporin A was added 72 h after the initiation of AMLR cultures eliminates the possibility of nonspecific toxic or lytic effects on the responding cells. Finally, activation of the stimulator cells with Epstein-Barr virus was not affected by the presence of cyclosporin A in the cultures, and pretreatment of the stimulator cells with this drug did not modify their capacity to induce proliferation (data not shown).

Fig. 1 Kinetic study of the inhibitory effect of cyclosporin A on the AMLR response. AMLR between 10^5 T cells and 10^5 irradiated autologous non-T cells were co-cultured in a final volume of 0.2 ml of complete culture medium (see Table 1 legend). Cyclosporin A ($1 \mu\text{g ml}^{-1}$) or medium was added to the cultures at different intervals after initiation of the AMLR cultures. Proliferation was determined by the ^3H -thymidine uptake during the last 12 h of the 7-day culture period.

Table 3 Response to various autologous stimulator cells of T cells from primary AMLR cultures performed in the presence or absence of cyclosporin A

Primary culture	Cyclosporin A addition ($\mu\text{g ml}^{-1}$)	Secondary AMLR culture stimulator cells				
		Non-T	T-PHA	T-AMLR	MNC-PHA	T-(AMLR + CYA)
T cells culture alone	—	$1.3 \pm 0.1^*$	1.8 ± 0.2	1.9 ± 0.1	2.4 ± 0.3	0.7 ± 0.1
	1	1.0 ± 0.1	0.7 ± 0.1	0.6 ± 0.2	0.9 ± 0.1	0.5 ± 0.1
T AMLR	—	33.4 ± 2.8	29.3 ± 1.7	20.6 ± 2.5	31.5 ± 1.9	2.9 ± 0.7
	1	6.3 ± 1.7	5.0 ± 1.8	4.8 ± 2.0	7.6 ± 2.3	1.1 ± 0.2
	3	4.2 ± 1.5	3.5 ± 0.6	3.3 ± 1.1	4.1 ± 1.6	1.4 ± 0.5
T AMLR + $1 \mu\text{g ml}^{-1}$ cyclosporin A	—	1.9 ± 0.1	1.3 ± 0.1	1.5 ± 0.3	4.2 ± 1.0	0.6 ± 0.1
T AMLR + $3 \mu\text{g ml}^{-1}$ cyclosporin A	—	1.1 ± 0.3	1.0 ± 0.1	1.4 ± 0.4	4.1 ± 0.7	0.9 ± 0.3

Cyclosporin A (1 or $3 \mu\text{g ml}^{-1}$) or medium was added to each well at the initiation of the secondary AMLR culture. T cells cultured alone or with irradiated autologous non-T cells in the presence (T-AMLR + 1 or $3 \mu\text{g ml}^{-1}$ cyclosporin A) or absence (T-AMLR) of cyclosporin A for 10 days (primary AMLR culture) were recovered by rosetting with SRBC and restimulated with the following autologous cells: Non-T cells; T-PHA = 8-day PHA-stimulated T cells; T-AMLR = T cells from 7-day cultures; MNC-PHA = 4-day PHA-stimulated peripheral blood MNC; T-AMLR = T cells from 7-day AMLR culture done in the presence of $1 \mu\text{g ml}^{-1}$ cyclosporin A. The cell mixture was incubated at 37°C for 3 days, and the ^3H -thymidine incorporation during the last 12 h of the culture period determined (see Table 1 legend).

* Mean $\pm$ s.d. of three independent experiments expressed as c.p.m. $\times 10^{-3}$.

We next studied the effects of cyclosporin A on the secondary AMLR using different kinds of irradiated autologous cells as stimulators. T cells activated in primary AMLR cultures or by PHA possess DR antigens on their surface^{9,12,13} and can function as stimulator cells in the AMLR⁹. Table 3 shows that the addition of cyclosporin A at the start of the secondary AMLR cultures inhibited the proliferation of the responding T cells. Interestingly, T cells from primary AMLR cultures performed in the presence of cyclosporin A were unable to function as stimulators in secondary AMLR cultures, whereas T cells from primary cultures without cyclosporin A functioned well as stimulator cells. Furthermore, the former cells were not killed by treatment with a monoclonal anti-DR antibody (NE011, NEN) plus complement whereas 50–60% of the latter cells were lysed by similar treatment. This indicates that T cells exposed to cyclosporin A lose their capacity to bind DR antigens, a property of T cells which has been demonstrated by Elliot *et al.*¹⁴

We also found that T cells from primary cultures containing cyclosporin A exhibited a proliferative activity similar to that shown by the population of cultured, not stimulated, T cells, whereas non-cyclosporin A-treated T cells responded with a typical pattern of secondary responses (higher proliferation at an earlier time). These findings suggest that cyclosporin A-treated T cells were not activated in the first culture, as they proliferate in secondary cultures to a similar extent to T cells cultured but not activated.

Thus, cyclosporin A inhibits the AMLR response by acting selectively on the responding T cells before they become responsive to IL-2, after which the drug can no longer inhibit T-cell proliferation and/or growth. We therefore conclude that cyclosporin A exerts its inhibitory effects by interfering with the process which normally enables resting T cells to become sensitive to IL-2, a step which is induced by signals from HLA-DR antigens of the stimulator cells^{9,10}. As cyclosporin A has no effect on stimulator cells, it probably blocks the receptors for the DR molecules on T cells and consequently inhibits the expression of IL-2 receptors on these cells. This notion is supported by several pieces of evidence. First, cyclosporin A-treated T cells are unresponsive and unable to absorb IL-2 (ref. 5 and the present study). Second, T cells from primary AMLR cultures performed in the presence of cyclosporin A do not possess DR antigens and are unable to function as stimulator cells in the AMLR. Third, cyclosporin A does not affect other receptors present on T cells, as it did not reduce the number of T cells forming rosettes with sheep red blood cells or autologous erythrocytes (data not shown).

We have recently found that HLA-DR antigens participate in the process of IL-2 production in either the AMLR or allogeneic mixed lymphocyte reaction (MLR) by rendering IL-2-producer T cells sensitive to interleukin 1 (formerly lymphocyte activating factor), which induces these cells to secrete the growth factor. The addition of cyclosporin A to AMLR and MLR cultures

causes IL-2-producer T cells to become unresponsive to interleukin 1 and abrogates the synthesis of IL-2¹⁵.

Role of RNA transcripts in replication incompatibility and copy number control in antibiotic resistance plasmid derivatives

Jonathan Rosen*, Thomas Ryder, Hisako Ohtsubo & Eiichi Ohtsubo

Department of Microbiology, School of Medicine, State University of New York at Stony Brook, Stony Brook, New York 11794, USA

The genes required for autonomous replication and incompatibility in the antibiotic resistance plasmids R100 and R1 have been located within a 2.5-kilobase region of the 90-kilobase genome, within which the incompatibility gene occupies a 1.3-kilobase region excluding the replication origin. We now report that three RNA species are synthesized *in vitro* from the 2.5-kilobase region, which R100 and R1 have in common. One, a long RNA molecule which is transcribed in the direction of DNA replication, probably acts as a messenger or a protein required for plasmid replication. The second RNA species, only 91 nucleotides long, is transcribed in the opposite direction, from a region of the DNA entirely contained within the first and known to specify incompatibility and copy control functions. The third RNA species, 150 bases long, is transcribed from a region including the replication origin¹; it may be a primer of DNA synthesis or, in conjunction with the second of the three RNA species, an influence in the control of replication.

When the *Pst*I fragment which carries the origin of replication of pSM1 or pTR1 is transcribed *in vitro* in the presence of

Fig. 2 Autoradiogram of a sequencing gel of the 5' end of RNAI. The position of selected G residues on the sequence shown in Fig. 3 are marked. Sequencing was performed by enzymatic cleavage as described by Donniss-Keller *et al.*¹⁵ and Simoncsits *et al.*¹⁶. The lanes of the gel are as follows: C, control; P, Phyl; A, pancreatic RNase A; L, alkaline digest; U, RNase U₂; T, RNase T₁. RNA was synthesized *in vitro*, basically as described by Majors¹⁷ in a mixture containing 0.2 pmol DNA (circular plasmids or linear restriction fragments) 30 mM Tris (pH 8.0), 2 mM MgCl₂, 0.1 M KCl, 0.1 mM EDTA, 0.1 mM dithiothreitol and 0.5 mg ml⁻¹ bovine serum albumin. RNA polymerase (Boehringer Mannheim) was added in a molar ratio of 10:1 enzyme to DNA and the mixture was incubated for 10 min at 37°C. Nucleotides were added to a final concentration of 20 µM except for the labelled nucleotide, which was added to 2 µM. The mixture was then transferred to a tube containing 40 µCi [α -³²P]UTP or 0.2 mCi dried down [γ -³²P]ATP¹⁸ or [γ -³²P]GTP (>1,000 Ci mmol⁻¹, ICN) and incubated at 37°C for 30 min. The transcripts were purified by gel electrophoresis as described by Donniss-Keller *et al.*¹⁵

[γ - ^{32}P]ATP, a third transcript called RNAIII is found. The 5' end of this transcript occurs at nucleotide 2,316, and the region upstream of this site displays moderate homology to prototypical promoter sites (Fig. 3). The transcript has two termination sites when this *Pst*I fragment is used as a template, the first being simply the end of the *Pst*I fragment, and the second at approximately nucleotide 2,465, about seven bases upstream of the *Pst*I cutting site. Label is preferentially incorporated in the shorter transcript with a ratio of 3.7:1. The sequence in this region, TAATCAATAT, is remarkably similar to that at the termination site of λtR1 -CAATCAA⁴-and tRNA_i^{Tyr}-CAATCAATAT⁵-both of which are ρ -factor-dependent transcriptional termination sites.

Fig. 1 A circular representation of some genetic and physical properties of the plasmid R100. The region required for replication (REP) includes the origin of replication (*ori*) from which replication proceeds unidirectionally in the direction shown. The origin region was determined by electron microscopic analysis of replicating molecules¹⁴ and the sequence was determined¹. The figure also shows a linear representation of the replication regions of the R100 derivative pSM1 and the R1 derivative pTR1 which was constructed from Rsc13 such that only the replication region and the gene conferring ampicillin resistance remain (T.R., unpublished results). The regions required for replication and incompatibility are shown at the bottom of the figure. The open arrows marked RepA3 and RepA4 indicate open reading frames predicted by nucleotide sequence analysis². The cross-hatched arrows show the position of reading frames whose polypeptide products have been confirmed². The heavy arrows marked RNAI, RNAII and RNAPIII are the transcripts described in the text.

* Present address: Department of Pathology, Stanford University School of Medicine, Stanford, California 94305, USA.

Fig. 3 The location of RNAI and RNAII within a *Pst*I fragment of pTR1. The entire sequence of the plasmid pSM1 within this fragment is shown and the differences between pSM1 and pTR1 are shown below the pSM1 sequence. The heavy lines above and below the sequence show the location of RNAI and RNAII at the nucleotide sequence level. The boxed regions proximal to each transcript delineate the Pribnow and -35 recognition sequences. The coding regions for RepA1 and RepA3 as well as the amino acid residues encoded are indicated on the sequence. A portion of the sequence of the origin region of pSM1 (2,260-2,480) including RNAIII and the sequence complementary to the 5' end of RNAI is also shown.

RNAIII has only been found when the linear *Pst*I fragment is transcribed, and its absence when superhelical pSM1 or pTR1 DNA is used as template may be due to nonspecific termination in the absence of ρ -factor yielding a heterogeneous range of transcripts. Most interestingly, the region of complementarity between RNAI and the origin region occurs within this transcript (Fig. 3). As will be discussed below, the interaction between RNAI and the superhelical template may affect the transcription of RNAIII.

RNAII is almost certainly the messenger RNA required to translate a 33,000-molecular weight (MW) protein called RepA1 which is assumed to be necessary for replication initiation (see Fig. 1 and ref. 2). As RNAII spans the coding region of a second, much smaller hypothetical 7,000-MW protein called RepA3, it may also direct the synthesis of that protein. However, RepA3 has not been seen *in vivo* or *in vitro*, so it is unclear whether this hypothetical protein is translated.

An interesting hypothesis is that RNAI may be partly responsible for copy number control and incompatibility, because it is synthesized in the region responsible for these functions. Figures 3 and 4 show that the two sequence differences between pSM1 and pTR1 in this region occur at the top of the proposed secondary structure for RNAI. Comparison of these sequences with the wild-type R1 DNA sequence recently obtained by Stougaard *et al.*⁶ reveals a single base-pair change between wild type and pSM1 at position 505 and

between wild type and pTR1 at position 510; these two differences between the pSM1 and pTR1 DNA sequences are probably responsible for their mutant copy number phenotypes, possibly altering the copy number and incompatibility properties of these plasmids by altering the affinity that RNAI has to a protein also involved in replication control.

RNAIII is likely to act either as the actual primer for the initiation of the plasmid DNA synthesis, or as a transcriptional activation signal which we suggest alters the conformation of a secondary structure at the replication origin upstream of this RNA transcript much as proposed by Hobom *et al.* for λ replication⁷. A large secondary structure has in fact been found upstream of RNAIII in pSM1 (ref. 1). As described above, 13 of the first 14 nucleotides of RNAI are complementary to the region between 2,367 and 2,380 of the replication origin region spanned by RNAIII (Figs 3, 4). Assuming that RNAI is involved in the incompatibility reaction and acts directly at the origin, RNAI may inhibit the initiation of DNA synthesis by binding to the complementary sequence at the origin region, probably with the aid of a protein(s).

In our *in vitro* system, RNAI and RNAII are transcribed simultaneously from the same region of the plasmid but in opposite directions. *In vivo*, the production of RNAI itself may be controlled at the transcriptional level by an attenuator-like mechanism^{8,9} affecting both copy number and incompatibility. If a ribosome succeeds in binding to a nascent RNAI before the

Fig. 4 Possible secondary structure of RNAI and homology to the origin of pSM1. The two arrows at the top of the loop indicate the differences between the sequence of RNAI and pSM1 and pTR1 at positions 505 (A→C) and 510 (C→U). The line within the first small hairpin loop indicates the region complementary to the origin region between nucleotides 2,367 and 2,380 of the pSM1 replication region sequence (see Fig. 3 and ref. 1).

RNA polymerase reaches the termination point the secondary structure would be disrupted and, analogously to the pattern of transcription in attenuation systems^{8,9}, transcription might proceed beyond the termination point reported here. It is difficult to predict if RNAI is actually translated. A small open reading frame begins at the start codon GUG (535–533) just before the large stem structure seen in Fig. 4 and continues until the termination codon UAG (384–382) (see Fig. 3). This reading frame is preceded by the sequence GGU (542–540), which may serve as a ribosome binding site¹⁰. The protein which could be translated from the extended RNA would have a MW of ~5,300, and as this is the region encoding copy number control and incompatibility functions, both of which are probably controlled by a repressor from this region, the 5,300-MW polypeptide is a possible candidate. However, because the base-pair change between pSM1 and R1 would not cause an amino acid change if the extended RNAI were translated, this small polypeptide would be identical in the wild-type and mutant plasmids. The two modes of transcription of RNAI may, however, correspond to the repressed and derepressed states of replication. Thus, the rate of plasmid replication could be tied, deterministically, to other aspects of cellular metabolism by the average rate of initiation for RNAI translation. This larger RNA species may no longer be effective either because of steric problems in binding at the origin or in forming a duplex with nascent RNAII or because of improper or altered processing of the molecule.

Recent data obtained in the ColE1 plasmid system shows a very similar pattern of transcription in the region required for replication to that seen in pSM1 and pTR1 (ref. 11), although the ColE1 plasmid does not require any of its own proteins for replication and has no transcript corresponding to RNAIII. A small RNA which may be analogous to RNAI is produced in the direction opposite to the direction of replication and ~450 bases upstream from the replication origin¹². A small insertion mutation that maps in this RNA increases the copy number of the plasmid, indicating that this RNA is an important control element¹³. Furthermore, it is transcribed in the direction opposite that of a second, larger transcript required *in vitro* as a primer for DNA synthesis¹¹. We do not know whether RNAII in our system can be used as both an mRNA and a primer for R-factor replication. It is reasonable to propose that RNAI, by interacting at the origin region, is involved in copy number control,

based on its location in the replication region, the changes found in pSM1 and pTR1 that appear to cause the increased copy number phenotype and by partial analogy to the ColE1 system. Further genetic and biochemical analyses to determine the nature of this control system are under way.

We thank Chiyoko Machida for sharing her expertise in the use of various RNases, Bert Semler and Naomi and Akiko Kitimura for help in the initial stages of RNA sequencing, Yvonne Tong and Linda Hollman for typing the manuscript, Joyce Schirmer for the illustrations and Jeff Demian for the photographs. This work was supported by the USPHS with research grants to E.O. (GM22007) and H.O. (GM26779) and by partial support to T.R. under training grant (CA-09176).

Note added in proof: In recent attempts to shorten the replication region we have been unable to delete the region coding for RNAI and RNAII but the region coding for RNAIII can be eliminated. Thus RNAIII is unlikely to be a primer for DNA synthesis but the possibility that its normal function includes some other aspect of replication control is not excluded.

An inducible DNA replication-cell division coupling mechanism in *E. coli*

Olivier Huisman & Richard D'Ari

Institut de Recherche en Biologie Moléculaire, 2, Place Jussieu
(Tour 43), 75221 Paris Cedex 05, France

Cell division is a tightly regulated periodic process. In steady-state cultures of Enterobacteriaceae, division takes place at a well defined cell mass¹ and is strictly coordinated with DNA replication². In wild-type *Escherichia coli* the formation of cells lacking DNA is very rare³, and interruptions of DNA replication arrest cell division⁴⁻⁶. The molecular bases of this replication-division coupling have been elusive but several models have been proposed. It has been suggested, for example, that the termination of a round of DNA replication may trigger a key event required for cell division⁴⁻⁸. A quite different model postulates the existence of a division inhibitor which prevents untimely division and whose synthesis is induced to high levels when DNA replication is perturbed⁹. The work reported here establishes the existence of the latter type of replication-division coupling in *E. coli*, and shows that the *sfiA* gene product is an inducible component of this division inhibition mechanism which is synthesized at high levels after perturbations of DNA replication.

Fig. 1 Inducibility of *sfiA* gene expression by thymine starvation and UV-ray irradiation. Bacteria were grown at 37°C in M63 minimal salts medium³⁵ supplemented with glucose, casamino acids and growth requirements. At an absorbance *A* of ~0.4, the cultures were adjusted to *A* 0.1, a part of each was induced (a, centrifuged and washed twice, then resuspended in medium without thymine; b, irradiated with 10 J m⁻² UV ray) and incubation was continued at 37°C. Samples were withdrawn every 5 (induced cultures) or every 15 (uninduced cultures) min for absorbance measurements and β -galactosidase assays (carried out as in ref. 35). Enzyme units were calculated as described in ref. 37. Strain construction is described in Table 1 legend.

Much evidence points to the induction by DNA damaging treatments of a number of biological phenomena, collectively termed the SOS response (reviewed in refs 10–12). These phenomena include the appearance of new DNA repair and mutagenic activities, massive synthesis of the *recA* protein, lytic development of certain prophages in lysogenic strains and division inhibition (filamentous growth) in non-lysogens. The *recA* and *lexA* functions regulate the expression of all these phenomena. Mutant alleles of either locus can entirely prevent induction of the SOS response (*recA*⁻, *lexA*⁻) or cause its gratuitous expression at 42°C (*tif* at the *recA* locus, *tsl* at the *lexA* locus)^{10–12}.

Incubation of non-lysogenic *tif* or *tsl* strains at 42°C arrests cell division, resulting in the formation of long, multinucleate filaments. This filamentous growth is completely suppressed by *sfiA* mutations, whereas other aspects of the SOS response are unaffected^{13–15}. The *sfiA* locus thus defines an element directly involved in the division inhibition process.

One model of replication-division coupling predicts the existence of an inducible division inhibitor. We thus sought to determine whether synthesis of the *sfiA* product is induced when DNA replication is perturbed.

To obtain accurate quantitative measurements of the rates of *sfiA* gene expression in various conditions we chose the powerful method of operon fusion, using the phage Mu d(Ap, *lac*)¹⁶ to link the structural gene for β -galactosidase (*lacZ*) to the promoter of the *sfiA* operon. Near one extremity of the phage genome are the *lacZ* and *lacY* genes, lacking a promoter. The phage genome is so constructed that, when inserted in a host operon in the proper orientation, the *lac* genes of the prophage can be expressed from the adjacent bacterial promoter: their level of expression then reflects the level of expression of the bacterial operon in which the prophage is inserted.

Previous studies have shown that *sfi*-dependent filamentation occurs early during thymine starvation¹⁷. The effect of thymine starvation on *sfiA* expression was investigated in a *thyA sfiA::lacZ* fusion strain. The differential rate of β -galactosidase synthesis in these conditions quickly increases 20–40-fold (Fig. 1a, Table 1) reaching ~0.3% of total protein synthesis. Thus the *sfi*-dependent filamentation normally observed during thymine starvation is correlated with a large increase in the rate of *sfiA* gene expression. A UV-ray dose of 10 J m⁻² similarly causes a rapid 20–40-fold increase in the differential rate of β -galactosidase synthesis (Fig. 1b, Table 1). Nalidixic acid, a specific inhibitor of DNA gyrase, and methyl methanesulphonate, a DNA alkylating agent, also induce high rates of *sfiA* gene expression (Table 1). A Mu d(Ap, *lac*) prophage inserted in the *gal* operon does not lead to UV-ray inducible β -galactosidase synthesis (Table 1), showing that the inducibility observed in *sfiA::lacZ* strains depends on the *sfiA* location of the prophage. We conclude that perturbations of DNA replication induce a high level of expression of the *sfiA* gene.

We next studied the effect on *sfiA* gene expression of mutations known to suppress or enhance *sfi*-dependent filamentation. *recA*⁻ and *lexA*⁻ mutations completely suppress the SOS

Table 1 Induction of *sfiA* gene expression

Strain	Inducing treatment	β -galactosidase specific activity (U per mg dry weight)		
		Un-induced	Induced	Dose
<i>sfiA::lacZ thyA</i>	Thymine starvation	50	410	
<i>sfiA::lacZ</i>	UV-ray irradiation	30	140	1 J m ⁻²
			440	10 J m ⁻²
<i>sfiA::lacZ</i>	Nalidixic acid	30	110	2 μ g ml ⁻¹
			710	40 μ g ml ⁻¹
<i>sfiA::lacZ</i>	Methyl methanesulphonate	30	360	0.025%
<i>sfiA::lacZ</i>	Nitrofurantoin	30	90	2 μ g ml ⁻¹
<i>sfiA::lacZ recA</i>	UV-ray irradiation	10	10	1 J m ⁻²
			10	10 J m ⁻²
<i>sfiA::lacZ lexA</i>	UV-ray irradiation	10	10	1 J m ⁻²
			10	10 J m ⁻²
<i>sfiA::lacZ tif</i>	42°C	80	700

	UV-ray irradiation	10	10	10 J m ⁻²
<i>gal::lacZ recA</i>	Galactose + UV rays	10	25	0.4%, 10 J m ⁻²
<i>gal::lacZ lexA</i>	Galactose + UV rays	10	30	0.4%, 10 J m ⁻²
<i>gal::lacZ tif</i>	42°C	10	10	

Bacteria were grown at 37°C in M63 salts medium³⁵ supplemented with glucose, casamino acids and growth requirements (except for the experiments with *tif* and *tsl* strains, grown at 30°C) to a value of *A*₆₀₀ of ~0.4, then diluted to *A* 0.1 (the thymine-starved culture was first centrifuged and washed twice to remove exogenous thymine). One part of the culture was induced (by removal of thymine, UV-ray irradiation, temperature shift or addition of the appropriate factors), the cultures were further incubated for 60 min and β -galactosidase specific activities measured³⁵. Adenine (100 μ g ml⁻¹) was added to the *tif* cultures at the time of the temperature shift. To isolate Mu d(Ap, *lac*) insertions at the *sfiA* locus, we selected for a Sfi⁻ phenotype^{13,25,26} in a *lon* strain²⁴, taking advantage of the hypersensitivity of the strain to low concentrations of nitrofurantoin³⁶. Lysogenic Sfi⁻ clones were selected from a Mu d(Ap, *lac*)-infected *lon* culture on plates containing ampicillin (50 μ g ml⁻¹) and nitrofurantoin (2 μ g ml⁻¹). These were purified, checked for UV-ray resistance (to confirm the Sfi⁻ character) and analysed genetically. All Sfi⁻ clones carried a *sfiA* mutation, about 50% co-transducible with *pyrD* by P1^{13,15,25,26}. For most isolates the introduction by transduction of the Sfi⁻ character was invariably accompanied by loss of the Mu d(Ap, *lac*) prophage; the strains thus harboured a single Mu d(Ap, *lac*) prophage, located at the *sfiA* locus and conferring a Sfi⁻ phenotype. Strains of this type having a significant basal level of β -galactosidase were considered to have the *lac* genes fused to the *sfiA* promoter. One such fusion was transduced with P1 *vir* (selection Ap^R) into a strain carrying a chromosomal *lac* deletion (to prevent extraneous synthesis of β -galactosidase) and a Mu c⁺ prophage inserted in the *trp* operon (to prevent thermoinduction of the Mu d(Ap, *lac*) prophage, whose repressor is thermolabile). One Ap^R transductant, verified to have a Sfi⁻ phenotype, was used for this study; all other *sfiA::lacZ* fusion strains were derived from this transductant. The *gal::lacZ* strains were constructed in a similar way using a strain carrying Mu d(Ap, *lac*) inserted in the *galT* gene as donor in the transduction to Ap^R.

Fig. 2 Regulation of *sfiA* gene expression in *tif(recA)* and *tsl(lexA)* mutants. Bacteria were grown at 30°C (a, in M63 minimal salts medium³⁵ supplemented with glucose, casaminoacids, growth requirements and—at 42°C—adenine; b and c, in LB broth). At A 0.4, the cultures were diluted to A 0.1 in medium prewarmed to 42°C (open symbols) or 30°C (closed symbols) and incubation was continued. Samples were withdrawn every 5 (42°C cultures) or every 15 (30°C cultures) min for absorbance measurements and β -galactosidase assays^{35,37}. Strain construction is described in Table 1 legend.

response¹⁰⁻¹². In *recA* or *lexA* derivatives of the *sfiA::lacZ* fusion strain no UV-ray induction of β -galactosidase synthesis is observed in the dose range 1–10 J m⁻² (compare with Table 1). These same *recA* and *lexA* mutations introduced into a *gal::lacZ* fusion strain do not affect the inducibility of β -galactosidase synthesis by galactose, and the capacity of these highly UV-ray sensitive strains to synthesize β -galactosidase is not seriously reduced by 10 J m⁻² UV-ray irradiation (Table 1).

The *tif* and *tsl* mutations in the *recA* and *lexA* genes cause constitutive expression of some SOS functions at 42°C (refs 18, 19), including *sfi*-dependent filamentation^{13,14,17}. At this temperature in *tif sfiA::lacZ* (Fig. 2a, Table 1) and *tsl sfiA::lacZ* (Fig. 2b, Table 1) fusion strains, a high rate of β -galactosidase synthesis is induced, but no similar induction is observed in a *tif gal::lacZ* fusion strain (Table 1). Furthermore, division inhibition by expression of the *tsl* mutations, unlike all other known inducing treatments, does not depend on *recA*⁺ activity²⁰ and in a *tsl recA sfiA::lacZ* fusion strain a high level of β -galactosidase synthesis is still observed at 42°C (Fig. 2c, Table 1).

The *recA*⁺ and *lexA*⁺ gene products are thus regulators of *sfiA* gene expression, probably at the transcriptional level. The *recA* and *din* genes are similarly inducible in a *recA*⁺–*lexA*⁺–dependent manner^{19,21}, and in the case of the *recA* gene this regulation has been shown to be at the transcriptional level^{22,23}.

The *lon* mutation²⁴ amplifies *sfi*-dependent filamentation^{13,25,26}, sensitizing the cell to small doses of DNA damaging treatments. At least seven different enzymes involved in cell-wall biosynthesis are present at higher levels in *lon* strains than in *lon*⁺ strains²⁷, and in one case, that of the *gal* operon, the *lon* mutant has been reported to have increased transcription rates²⁸. The induction of *sfiA* gene expression by UV-ray irradiation was identical in *lon* and *lon*⁺ *sfiA::lacZ* fusion strains in basal level and induction kinetics (see Table 1). Thus *lon*⁺ function does not seem to be a transcriptional regulator of the *sfiA* operon. As *lon* mutants are also deficient in Deg protease activity²⁹, it is tempting to speculate that this protease is normally involved in eliminating excess *sfiA* protein, allowing rapid resumption of cell division as soon as normal DNA replication is restored.

Current models accounting for the regulation of the SOS response postulate that DNA damaging treatments result in the formation of a signal molecule by the DNA replication complex³⁰⁻³². This molecule activates the *recA* protein to a protease form which, in turn, cleaves certain cellular repressors, in particular the *cI* repressor of λ prophage³³ and the *lexA* protein³⁴. The results reported here show that a high rate of *sfiA* gene expression is part of the SOS response. The *sfiA* product is directly involved in SOS division inhibition and its synthesis is induced very rapidly during thymine starvation or after UV-ray

irradiation (Fig. 1). The *sfiA* product thus provides a highly sensitive link coupling cell division to DNA replication by the following probable sequence of events: perturbations or alterations of the DNA replication complex cause the generation of a signal molecule which activates the *recA* protein to its protease form. The *recA* protease then cleaves the *lexA* repressor, leading to derepression of the *sfiA* operon. Finally, the high concentration of *sfiA* protein thus produced results in an inhibition of cell division. In this sense the *sfiA* gene product can be considered an inducible division inhibitor, although its precise role in division inhibition remains to be elucidated.

We thank Maxime Schwartz for providing a *gal::lacZ* fusion strain and Micheline Jaques for helping in experimental work. This work was supported in part by grants ATP 4185 (CNRS-INRA) and ATP 72-79-104 (INSERM). This letter is dedicated to the memory of Jacqueline George, whose enthusiasm and insight initiated the research.

† Department of Biochemistry, Animal Virus Research Institute, Pirbright, Woking, Surrey GU24 0NF, UK

Foot and mouth disease virus (FMDV), of the family Picornaviridae, consists of a single-stranded RNA (~8,000 nucleotides), the translation of which is initiated on the 3' side of a 150-nucleotide poly(C) tract and yields a single polypeptide which is processed by host cell proteases into four primary products (Fig. 1)¹⁻⁴. One or more virus-specified proteases further cleave these into the final products, the capsid proteins (VP1-4) being derived from the precursor p88 (for review see ref. 5). There are seven serotypes of the virus and as it has been shown that the immunizing activity of FMDV particles is associated primarily with VP1 (refs 6, 7), it seems likely that antigenic variation in FMDV is a result of changes in the structure of this protein. To further our understanding of this variation and as a first step in the possible development of FMDV vaccines from genetically manipulated microorganisms, we report here the construction and analysis of recombinant plasmids containing cDNA copies of the RNA. Comparison of the deduced amino acid sequence with the known polypeptide sequences shows that the NH₂-termini of VP2 and VP3 are conserved between the A and O serotypes whereas that of VP1 (the immunizing antigen) varies by as much as 42% between serotypes.

Using two strains of FMDV (serotypes A₁₀, strain 61 and O₁, strain BFS), double-stranded (ds) cDNA was synthesized⁸ and recombinant clones derived as described elsewhere⁹. Briefly, FMDV RNA (10 µg), primed with oligo (dT)₁₂₋₁₈, was used as a template for ds cDNA synthesis by reverse transcriptase. The ds cDNA so obtained ranged in size from 200 to 8,000 base pairs with a mean of ~1,000 base pairs as judged by agarose gel electrophoresis. The (dC)-tailed cDNA (0.05 pmol) was annealed with (dG)-tailed *Pst*I-digested pAT153 (0.2 pmol)¹⁰ and used to transform competent¹¹ *Escherichia coli* HB101 cells¹². Those clones derived from A₁₀ RNA are designated pFA10(61)/t whereas those from O₁ RNA are designated pFO1(BFS)/t; these are abbreviated here to pFA and pFO, respectively. In both the pFA and pFO clone banks ~90% of the tetracycline-resistant colonies were sensitive to ampicillin (100 µg ml⁻¹) which suggested that these colonies carried plasmids with ds cDNA inserted at the *Pst*I site. Further characterization was initially on the basis of size, using a modification of the single-colony lysis procedure¹³. The size distribution paralleled that of the ds cDNA used in the cloning (data not shown); the largest plasmid, pFA206, contained an insert of 5,800 base pairs.

Construction of restriction maps of the four largest plasmids from both sets of recombinants showed that, in the case of the pFA set, two plasmids, pFA76 and pFA206, contained overlapping ds cDNA inserts which together corresponded to ~7,200 base pairs (~90% of the FMDV genome). In the pFO set, the largest plasmid, pFO251, contained all the sequence (~4,800 base pairs) present in the other pFO plasmids analysed. The *Pst*I site was not regenerated at both ends of all of the inserts which were analysed, probably because of slight exonuclease degradation at some stage during the construction of the recombinants.

To align the restriction maps with the physical map of FMDV, ³²P-labelled fragments of type A₁₀ RNA produced by T₁ RNase digestion were used as probes. Two oligonucleotides, T₁-3 and T₁-4, were used initially as these are located 1,000 (±300) and 2,300 (±500) nucleotides respectively from the 5' end of the RNA¹⁴. Aliquots of a *Pst*I/*Ava*I double digest of pFA76 were resolved by agarose gel electrophoresis, transferred to nitrocellulose filters¹⁵ and probed with ³²P end-labelled oligonucleotides. The two probes hybridized to different fragments of the

Fig. 1 Organization of the FMDV genome. The relative positions of the genes on the FMDV RNA have been published elsewhere⁵. VP1, 2, 3 and 4 are the capsid proteins and are derived from the precursor p88. The ds cDNA inserts of four recombinant plasmids are aligned with this map on the basis of restriction endonuclease analysis, hybridization to ³²P-labelled T₁ oligonucleotides (see Fig. 2) and on DNA sequence analysis. The T₁ oligonucleotides 20 and 27 are positioned on the basis of previously published results^{14,19}, whereas oligonucleotides 3 and 4 have been located exactly as a result of the DNA sequence analysis. The regions of DNA sequence presented in

Fig. 3 are indicated by the heavy dots and arrowed lines over pFA76: a, b and c refer to the corresponding sections of Fig. 3. The restriction enzyme sites are designated: A, *Ava*I; B, *Bam*HI; E, *Eco*RI; G, *Bgl*II; H, *Hind*III; M, *Sma*I; P, *Pst*I; S, *Sal*I; X, *Xba*I; F, *Hinf*I. The *Ava*I and *Hinf*I maps have been completely determined for pFA76 only.

Table 1 Homology between the amino termini of VP1 of five FMDV strains

	A ₁₂	O _{1K}	O _{1B}	C _{3R}
A ₁₀	69	82	58 ± 4	71 ± 4
A ₁₂		65	73 ± 4	83 ± 4
O _{1K}			63 ± 2	67 ± 4
O _{1B}				73 ± 6

Percentage homologies were determined from the data presented in Fig. 3. The potential error accounts for the ambiguity in the published sequences.

digest (Fig. 2) and, as the relative positions of these restriction fragments in the pFA76 ds cDNA insert were known, the inserted cDNA could be aligned with the RNA to within 500 nucleotides and its orientation in the plasmid obtained. The results indicated that the pFA76 insert spanned from ~800 to 4,000 nucleotides from the 5' end of the genome and the insert in pFA206, as deduced by its overlap with pFA76, spanned from ~2,000 to 7,800 nucleotides from the 5' end. This alignment was consistent with the finding that T₁-20 (which had been mapped to between 500 and 1,000 nucleotides from the poly(A) tail¹⁴) specifically hybridized to the *Pst*I fragment of pFA206 nearest the 3' end (data not shown). The ds cDNA contained within these two recombinants therefore included the entire region coding for the major capsid proteins (Fig. 1).

The pFA recombinant clones were also screened by colony hybridization^{16,17} to detect plasmids containing inserts derived from the ends of the RNA. Short, oligo(dT)-primed ³²P-cDNA was used as a probe for plasmids containing sequences from the 3' end of the RNA; several colonies gave a positive signal with this probe. The sensitivity of this assay was increased by isolating DNA from 1-ml cultures of these recombinant bacteria¹⁸ and binding this DNA onto nitrocellulose filters. Oligonucleotide T₁-27, which is located 12–21 nucleotides from the 3' end of the RNA^{14,19}, was ³²P-labelled and used to probe such a filter. Only one recombinant clone (pFA243) gave a positive signal; by DNA sequence analysis, this recombinant was found to contain sequences corresponding to the 3' end of the virus RNA, including ~30 nucleotides of the poly(A) tail (data not shown). From a comparison of restriction maps, pFA243 and pFA206 overlapped by ~2,000 base pairs (Fig. 1).

To detect plasmids containing sequences from the 5' end of RNA ³²P-pCp-labelled S fragment, the small (~380 nucleotides²⁰), 5'-terminal fragment of the RNA produced by RNase H digestion in the presence of oligo(dG)₁₂₋₁₈ (ref. 3), was used to screen the recombinant clones. None of the clones gave a positive signal using this probe, which suggests that the 5' end of the RNA was not represented in the clone bank. In a similar hybridization with ³²P-labelled T₁-3 (located ~1,000 nucleotides from the 5' end, Fig. 1) only two recombinants (pFA76 and pFA187) gave positive signals (data not shown). Digests of pFA76 DNA were already known to hybridize with T₁-3 (Fig. 2, lane 3); further analysis of pFA187 by restriction endonuclease mapping showed that it extended only marginally further than pFA76 towards the 5' end (data not shown). These results indicate that ~750 nucleotides from the 5' end of the RNA are not represented in the recombinant clones.

An identical approach was used to orientate the pFO clones using the probes prepared from type A₁₀ RNA. This was possible even though there is only ~60% homology between the genomes of strains A₆₁ and O₁BFS²¹. Radiolabelled T₁-20 specifically hybridized to one fragment of a *Pst*I/*Eco*RI double digest of pFO251 (Fig. 2, lane 5). The orientation of the ds cDNA insert relative to the genome suggested by this result is supported by the similarity between the restriction maps of pFO251 and pFA206 (Fig. 1).

A detailed restriction map of pFA76 was constructed and used to sequence defined parts within the region coding for the structural proteins (Fig. 1). The sequences obtained around the junctions of these proteins are presented in Fig. 3 together with

the predicted amino acid sequences. The latter are compared with the partial amino acid sequences which have been published for these proteins derived from other strains and serotypes of FMDV²²⁻²⁴. The amino-terminal sequence of VP2 is identical in the A₁₀ and O_{1K} strains over the 20 amino acids available for comparison, while the amino terminus of VP3 shows just two differences out of 32 amino acids. The amino-terminal region of VP1 from A₁₀ can be compared with four other strains of FMDV (Fig. 3c). The relatively large extent of variation of the amino-terminal region of VP1 (compare with VP2 and VP3) may be related to the fact that this protein is the major immunizing antigen of FMDV^{6,7,25-27} and so variation of its sequence is under positive selection by the immune system of the host. The partial conservation of sequence which is apparent is probably due to constraints which must exist in order for VP1 to fulfill its function in the capsid and perhaps for the critical features of the protease cleavage site in p88 to be maintained. A comparison of the degree to which the sequences vary between strains (Table 1) shows no obvious correlation with the serological relationships of the different strains. However, as the region available for comparison constitutes only ~10% of VP1, it may be that the antigenic determinants which define its serotype lie elsewhere within the protein.

On the basis of their size and relative positions on the genome, it seems likely that the capsid proteins are contiguously coded²⁸.

Fig. 2 Orientation of ds cDNA inserts with FMDV genome. Restriction fragments of pFA76 and pFO251 DNA were resolved by electrophoresis through a 0.85% agarose gel, and transferred to nitrocellulose filters (Schleicher & Schuell BA85)¹⁵. The filters were then incubated in 30 μ l cm⁻² of hybridization buffer (40% (v/v) formamide, 0.4 M NaCl, 10 mM PIPES-NaOH pH 6.4, 0.5% (w/v) SDS, 0.04% (w/v) bovine serum albumin, 0.04% (w/v) Ficoll, 0.04% (w/v) polyvinyl pyrrolidone 40 and 100 μ g ml⁻¹ *E. coli* tRNA) for 2 h at 50 °C before addition of the ³²P-labelled RNase T₁ oligonucleotide probes. The probes were prepared by two-dimensional gel electrophoresis of an RNase T₁ digest of 100 μ g of ³²P-labelled type A₁₀ RNA (5 $\times$ 10⁵ c.p.m.)³. The oligonucleotides were eluted from the gel and labelled at the 5' end using polynucleotide kinase as described elsewhere³⁰. The probes were allowed to hybridize for 16–20 h at 50 °C before the filters were washed in 2 $\times$ SSC (eight changes of 250 ml each) at 45 °C, air-dried and autoradiographed for 24–28 h at –70 °C with an intensifying screen. Lane 1, ethidium bromide-stained gel of pFA76 DNA digested with *Pst*I and *Ava*I. Lane 2, parallel digest hybridized with ³²P-labelled T₁-4 (2.5 $\times$ 10⁵ c.p.m.). Lane 3, parallel digest hybridized with ³²P-labelled T₁-3 (4 $\times$ 10⁵ c.p.m.). Lane 4, ethidium bromide-stained gel of pFO251 DNA digested with *Pst*I and *Eco*RI. Lane 5, parallel digest hybridized with ³²P-labelled T₁-20 (5 $\times$ 10⁵ c.p.m.). The sizes of the restriction fragments in base pairs are indicated.

Fig. 3 Nucleotide and amino acid sequences at the junctions of the regions coding for the major capsid proteins. The nucleotide sequence of the positive strand of pFA76 was determined³¹ and used to deduce amino acid sequences in three regions (*a*, *b* and *c*; Fig. 1). The boundaries of the putative coding regions (↓) were set as described in the text. The amino acids are numbered from the amino-terminus of VP2, VP3 and VP1 in *a*, *b* and *c*, respectively. The published carboxy-terminal sequences (COOH) are from ref. 22; the published amino-terminal sequences (NH₂) from ref. 23 (type O_{1K}) and ref. 24 (types A₁₂, O_{1B} and C_{3R}). The underlined residues indicate homology between the A₁₀ sequence and the published data (ambiguities in the published amino-terminal sequences of VP1 are assumed to conform, where possible, to the consensus sequence).

The limited comparisons presented in Fig. 3 are consistent with this hypothesis: the sequence (Thr-Gln) which immediately precedes the amino terminus of VP1, is very similar to the published carboxy terminus of VP3 (Ser-Gln) from a different strain; the difference (Thr rather than Ser) is conservative with respect to charge and hydrophobicity. As the comparison for the carboxy terminus of VP2 is limited to only one residue (albeit identical with the published datum) and there are no comparative data for VP4, a definite conclusion on the contiguity of the structural polypeptides in p88 must await more extensive peptide analysis. Nevertheless, it is clear that the amino acid sequences at three proteolytic cleavage sites within p88 differ in both the type and identity of the amino acids.

VP1 purified from chemically disrupted virus particles has been shown to elicit low levels of neutralizing antibody in pigs and guinea pigs and to protect pigs against the disease²⁵⁻²⁷. An alternative approach to producing a vaccine therefore might be to prepare VP1 from genetically manipulated microorganisms. The recombinant pFA76 contains the sequence encoding all of p88 plus part of both p20 and p52. Such a plasmid offers the option of genetically engineering bacteria so that they synthesize all the capsid proteins in one precursor. This may have advantages over synthesis of VP1 by itself because in the normal replication cycle of FMDV, all capsid proteins are synthesized via the p88 precursor and this may influence their final conformations and immunological properties. Recombinant clones containing the coding sequences of all the capsid proteins, such as pFA76 described here, provide a starting point for such developments.

While this manuscript was in preparation we learned of similar work being done by Küpper *et al.*²⁹ on FMDV strain O_{1K}.

We thank Ruth Ashforth, Sharon Coleman and Cora Paynter for technical assistance and Drs J. Beard, R. B. Flavell, A. Newman, D. Sherratt and R. Thompson for gifts of materials and/or advice.

BOOK REVIEWS

Newton unravelled

Marie Boas Hall

AS Voltaire remarked 250 years ago, few people read Newton because to do so intelligently one must be learned, but everybody talks about him. All scientists know a little of Newton but few know much, nor has it been easy to unravel the details of his life and work. For well over a century and a half scholars have known that Newton left a great mass of manuscript material; only over the past 30 years has it been studied seriously, transcribed and commented upon; and until now the standard biography has been that of David Brewster, published in 1855. Brewster had access to most of the manuscripts but though the Royal Society tried to make them accessible they were not finally deposited, in part, in the Cambridge University Library until 1888. No subsequent biographer utilized them, although Louis Trenchard More used and partly published some papers retained in private possession in his biography of 1934.

When Professor Westfall began work 20 years ago on this monumental scientific biography, destined to become the standard *Life* for the foreseeable future, he knew he must plunge into manuscript sources, for only Newton's *Correspondence* was in course of publication. As he worked, so the mathematical papers have been published *in extenso* by D.T. Whiteside, while many of the papers relating to the *Principia* and *Opticks*, early notebooks, thoughts on the nature of matter, selections from his historical, theological and alchemical manuscripts and numerous minor works have appeared with scholarly commentary, creating what Westfall, who has himself contributed to it, has called "the Newton industry".

Never at Rest is an able and thorough study of Newton the man and the scientist, especially and inevitably the latter who is both the more enduring and the better documented — almost too well documented. Newton was a compulsive scribbler: he read pen in hand, taking notes, making comments, writing and re-writing, analysing, commenting, organizing, drafting and redrafting, and seldom or never destroying.

Professor Westfall has worked through a great deal of the available manuscript material and presents a detailed account — careful, clear and judicious. First comes an analysis of the intellectual background of the day, then Newton's initiation into it,

Never at Rest: A Biography of Isaac Newton. By Richard S. Westfall. Pp.960. ISBN 0-521-23143-4. (Cambridge University Press: 1980.) £25, \$49.50.

Isaac Newton, man of many talents

Mary Evans

then his first steps towards original thought (in his reaction to Descartes' philosophical position) and his very first attempts at mathematics. Soon, leaping over conventional Euclidean geometry, Newton was deep into and going beyond contemporary developments in what we call analysis and he called "resolving problems by motion" (1665) and "the method of tangents", and "analysis by infinite series". In 1669, he showed a paper on the last subject (*De analysi*) to Isaac Barrow, first Lucasian Professor of Mathematics. Barrow immediately recognized its worth and when John Collins (a mathematical news monger, remembered for his

collection of contemporary letters published by Rigaud in 1841) sent him a new book which touched on series, Barrow in return sent *De analysi* (whence, in fact, news of the rising mathematician reached the Royal Society and through its secretary, Oldenburg, passed to Continental mathematicians). Had either Barrow or Collins been more adroit, *De analysi* would have been published and much later controversy avoided. When Barrow soon after resigned his professorship, Newton succeeded him; Westfall agrees with the tradition that Barrow's influence was here paramount.

Although Newton continued to work on and off at mathematics, he lectured on optics in which he had been interested for some years. The Latin lectures were deposited in the University Library as the regulations required, to be published only posthumously, but they became also Book I of the English *Opticks* in 1704, dealing with prismatic phenomena and dispersion. Soon Newton was led to the invention of the reflecting telescope, and of this, as he did not with mathematics, he wrote and spoke freely. The Royal Society learned of it in December 1671, elected him a Fellow, and with his permission both published an account and sent a written description to the Continent. Soon Oldenburg tactfully extracted Newton's first optical paper, with permission to publish it in the *Philosophical Transactions*. Although the Society praised the paper, it was by no means universally approved: Hooke, the Society's Curator of Experiments, an established scientist whose views Newton had earlier studied in *Micrographia* (1665), was acrimoniously and rudely critical; from Paris, Pardies (later a convert) and Huygens were politely so. Newton patiently answered their objections and in 1675, in the midst of controversy with the English Jesuits at Liège, sent his "Hypothesis on light and colours", whose publication he did not then permit. Yet he never blamed Oldenburg; indeed, after the latter's death in 1677, Newton told Hooke that he intended to publish his optical papers as Oldenburg had desired. Some sheets were printed, but the book never appeared — Westfall believes because of accidental destruction by fire.

Meanwhile Newton's interest was elsewhere — in chemistry or alchemy, an interest first aroused by his reading of

Boyle, and then increasingly by the avid study of the vast literature of alchemy, on which he made incredibly extensive notes. He was an able experimenter, so much his notebooks reveal. There is no doubt that he thought alchemists rational, and believed that their strange language could be mastered. Evidently he believed that he understood alchemical symbolism; unfortunately he never translated it, and the key to his experimental programme is thus lost. Westfall believes that Newton's theory of attractive force was the outcome of this work — a debatable view. Newton never completed any papers on chemistry, and only one fragment was published in his lifetime, an incomplete theory of acids in the *Lexicon technicum* (1710) of John Harris. (Westfall unaccountably overlooked this publication, though he knew of other contemporary copies.) Many of Newton's views appear in drafts for a conclusion to the *Principia*, and were added to the *Queries* in *Opticks* in 1706 and 1710, in abbreviated form. At this time Newton also turned to theology, seeking for "primitive" Christianity and becoming a convinced, though secret, Arian.

But during these years he continued to work occasionally on mathematical and mechanical problems. Thus it is not very surprising that he could readily rise to Halley's challenge in 1684, to take up the problem of the Solar System in deep mathematical detail and produce, first a treatise *De motu* and then, under the Royal Society's encouraging praise and Halley's tactful prodding, the triumph of the *Principia* (1687). Westfall discusses the development of the work at some length, though there is more detail in the later chapter on Newton's revisions for the second edition (1713), when Newton was still working on major problems in old age, though less brilliantly.

With the publication of the *Principia*, whose importance was universally recognized, Newton's productive scientific life came near to an end. Perhaps, at 45, he knew it; at any rate, like many scientists he turned to other things. He was active in university affairs in 1688 and Member of Parliament for the University. He began to look for outside preferment, which he did not at once find. He suffered a brief mental breakdown in 1693. Westfall, totally rejecting Manuel's Freudian interpretation, for sound reasons, and equally the recent suggestion of mercury poisoning, ascribes it to a complex variety of factors, not least the mental exhaustion produced by the creative achievement of the *Principia*. Newton recovered, secured his job in London in 1696 as Warden (and later Master) of the Mint, and filled the posts with energy and distinction. In 1703 he became President of the Royal Society, here also showing both administrative ability and energetic dominance. Inevitably, he embarked on no new scientific work, although even in his seventies he was still capable of skilful application when

stimulated. He put *Opticks* into print, and revised it. He worked with Cotes on the second edition of the *Principia* from 1709 to 1713, while still busy at the Mint, and actively engaged in the vituperative dispute with Leibniz over the invention of the calculus. (Each refused to believe that the other had independently developed it, and each was driven on by hot-headed disciples.) The consequences of Newton's earlier failure to publish came home to roost. In extreme old age he turned again to theology, and to Biblical chronology; as with alchemy he sought reason and logic in mystical writings. He became the leading scientist of the first quarter of the eighteenth century, dominating optics, mechanics and mathematical astronomy; only the new mathematics owed nothing to him.

What of Newton the man? The biographical details are meticulously set out here as far as they exist: his family origins, his relations, his schooling, his life at Cambridge and in London. I find Westfall less successful in reconstructing Newton the man than Newton the scientist, whom he clearly prefers. Many of Newton's less agreeable characteristics were common in his day: his reluctance to publish and jealousy over priority were

shared by Huygens, as well as by many others. Was he really so isolated at Cambridge as tradition suggests? He got preferment early, and all his life he attracted and kept the loyalty of many young men. In the priority dispute he seems pathologically paranoiac; so does Leibniz; neither was attractive. In his old age Newton was clearly domineering, easily provoked to anger, impatient of lesser minds, vain and unjust to adversaries — he was never Voltaire's passionless hero. But neither was he totally and disagreeably ungenerous in his dealing with others, especially in his prime.

Never at Rest will be warmly welcomed by Newton scholars, although they will inevitably dispute some points. (Some may feel that Westfall in sticking so close to manuscript sources has been less than generous to earlier labourers.) The book is not easy going, but it provides a masterly, well-documented summary of contemporary views of all the many facets of Newton's astoundingly wide-ranging career which will be novel to all but the specialist, and will be essential reading for aspiring Newtonian scholars. □

Marie Boas Hall retired as Reader of History of Science and Technology at Imperial College, University of London, in 1980.

America and China: lessons from the past

Douglas P. Murray

American Science and Modern China 1876-1936. By Peter Buck. Pp.283. ISBN 0-521-22744-5. (Cambridge University Press: 1980.) £15, \$24.95.

THE recent and rapid embrace of Americans and Chinese has proceeded with little reflection on the troubled history of their cultural interactions. Inherent in this heavy but rewarding book is a call for caution lest we be fated "to repeat elsewhere the failure of American science in modern China". Not only elsewhere, but perhaps again in China itself.

Although Peter Buck describes his book as "an essay in comparative history", he is concerned far less with comparison than with the interaction of two societies that seemed destined to miss each other. He analyses the motives, problems and impact of those pioneers of modern science involved in the cross-cultural transmission of ideas and institutions during the late nineteenth and early twentieth century. Their failure is Buck's fundamental thesis, judged upon the stated goals of America's scientific missionaries and the view that modern science through the 1930s remained "wholly marginal to Chinese life". Yet in the sweep of his complex social history the criteria for what might have been success remain obscure; the legacy of American science that clearly is influencing

the People's Republic of China today is generally ignored.

As reflected in 25 pages of footnotes, the volume is meticulously researched, drawing liberally from, but not duplicating, the important work of other recent analysts of the West's educational impact in China. Buck's focus is somewhat different and original: the "transfer of scientific ideas and institutions to China primarily for what it shows about the United States, and only secondarily because of its bearing on Chinese scientific development" (p.1).

In a brief introduction, Buck assesses our own nineteenth-century debates about the proper role and social power of science and medicine, and his first chapter traces how these conceptions were developed and then acted out in China through medical missionaries. Chapters 3 and 4 focus, respectively, on the subsequent evolution of "laboratory science" (seen by one writer of the time as a "retreat . . . far removed from the strife of sects or wayward passions of the day") and its expression in the China Medical Board and Boxer Indemnity Scholarship program, and on the social origins and orientations of the US-trained scholars who in 1914 founded the Science Society of China.

Buck then returns to the United States to investigate the role of Cornell University

which by 1910 was, with Harvard, "enrolling more Chinese than any other American college" and, indeed, was the birthplace of the Science Society of China. As in the preceding chapter, the author-historian turns sociologist and here covers the most interesting ground. Viewing the development of American science in the context of a society undergoing industrialization, he demonstrates how Chinese were trained in the US for a world that would not exist for them at home and how "in formulating their plans for scientific development, the Science Society's leaders filtered out much of the social content with which American scientists had invested their images of research and laboratory science" (p.164). But, for Buck's purposes, the more critical point comes later, in Chapter 6: the result only further underscored how thoroughly interpretations of these ideals varied, even in the United States . . . In industrial America, Chinese scientists saw integration and order, whereas in reality there was intense conflict and turmoil . . . their image of American industrialization owed more to the ideals of American scientists than to the actual American experience (p.206).

American conceptions of science tended to reach China after they already had changed or been challenged at home.

In a concluding chapter covering the 1920s and 1930s, Buck reviews the belated awakening of China's scientists to their dilemmas both in making science socially relevant and in coming to terms with the growing disappointments of their American benefactors. Yet, ironically, Chinese scholars also were becoming "progressively more convinced that the proper audience for their scientific work lay outside their country", with the international community (p.224). Making a rare link to more recent times, the author notes Mao Zedong's complaint about the behaviour of China's scientists before 1949:

He understood that they were not hostile or indifferent to the Chinese revolution, but from his perspective their enthusiasm for science involved a distinctive evasion of reality; [they mistakenly] 'stayed away from politics' (p.231).

Buck suggests a similar message for the West: detached from social context and public purpose, the best of science can be irrelevant. Our experience with China is the tapestry on which his message is woven.

In principle, this book should be required reading for all in the West now involved in or contemplating academic or technical cooperation with the PRC. Unfortunately, in practice it probably will appeal to a limited audience of scholars — those partial to the complex argumentation of an historian-philosopher whose commitment to grand concepts, intellectual rigour and direct quotation from a myriad of sources often makes the story hard to follow, or at least to enjoy. □

Douglas P. Murray is Director of the US China Relations Program at Stanford University.

Catching up with synchrotron radiation

Yves Farge

Synchrotron Radiation Research. Edited by Herman Winick and S. Doniach. Pp.754. ISBN 0-306-403-63-3. (Plenum: 1980.) £40.95, \$65.

THE past decade has seen an exponential growth in the use of synchrotron radiation — emitted by relativistic electrons in the bending magnets of storage rings — as an experimental probe. A consequence of this rapid advance is that, as in so many other fields, a book on the subject is already dated by the time it appears; this volume is no exception. Many of the 22 contributions will appear obsolete to the specialist, yet they do give a clear view of progress in synchrotron radiation research and of how its application is spreading from physics into chemistry, biology and applied sciences.

The first and last contributions are devoted to a discussion of how photons are generated by electrons passing through bending magnets. This radiation can range in wavelength from infrared to X-rays, is of very high intensity and its pulsed form can be used. Other advanced ideas, such as the use of wiggler or undulator magnets, which are now being tested on storage rings, and the development of a free-electron laser using undulators on these machines, are also discussed. In the remainder of the first part of the book, vacuum, ultraviolet and soft X-ray experiments on atoms, molecules and solids are considered; topics covered include absorption, fluorescence (radiative lifetimes and time-resolved spectroscopy) and photoelectron spectroscopy. These chapters give the reader a good view of the different kinds of electronic excitations which can be observed in such systems. One flaw, however, is that the chapter on photoelectron spectroscopy in solids is incomplete in that angle-resolved analysis of photoelectron spectra is largely ignored; even in 1978, from when most of the contributions date, this technique was known to be an important tool for band-structure determination in solids.

Of the later contributions, those on X-ray absorption spectroscopy are particularly good: Kronig's oscillations or EXAFS can provide useful structural information about a specific chemical element in inorganic as well as organic or biological samples. For example, study of the detailed structures of absorption edges reveals information about ionicity and coordination of the absorbing element.

The chapters on X-ray scattering provide an introduction to a field which was in its infancy at the time of writing (small-angle X-ray scattering, protein crystallography); they are mainly concerned with biological applications. Discussions of various applications, such as topography, X-ray fluorescence analysis, X-ray imaging and microscopy, complete the book.

This volume will be useful to non-specialists, as well as those already using synchrotron radiation in their research. One drawback is that work carried out at Stanford is emphasized at the expense of that performed in Europe, the USSR and Japan. However, the book clearly illustrates the revolutionary implications of the introduction of the technique into the natural sciences and is a cogent argument for the need for new machines designed specifically for the production of synchrotron radiation, some of which are under construction in several countries. □

Yves Farge was formerly Director of the French Synchrotron Radiation Facility (LURE), and is Chairman of the Synchrotron Radiation ad hoc Committee of the European Science Foundation and Scientific Counsellor at the Secrétariat d'Etat à la Recherche.

Reactions on a leash

Johannes Meienhofer

Polymer-Supported Reactions in Organic Synthesis. Edited by P. Hodge and D.C. Sherrington. Pp.484. ISBN 0471-277-12-6. (Wiley: 1980.) £29.50, \$88.

SOLID-PHASE synthesis of peptides and, recently, of oligonucleotides has received widespread attention, due in part to the interesting biological activities of these substances. Somewhat less notice has been given to the development of an impressive variety of polymer-supported organic chemical reactions in which a reagent, a catalyst or a substrate is attached to a polymer. There was a need to gather all aspects of polymer-supported organic synthesis into one volume, a task that the editors have accomplished admirably. A multitude of interesting reactions in many areas of chemistry is presented in 10 chapters, each written by an expert.

The opening contribution by D.C. Sherrington provides the reader (including the novice) with a solid base for understanding both the nature and the potentials of solid-support systems, in particular of the polystyrene type. P. Hodge then considers polymer-supported reagents. Oxidations, reductions and substitution reactions, condensing and acylating systems, solid phase ylids and organometallic reagents are presented. The large amounts of data are clearly organized in 42 well-designed tables and discussions of reaction mechanisms are aided by many schemes, equations and structures.

Sherrington discusses catalysis by ion-exchange resins and related materials, including a survey of transfer catalysis. Opportunities and constraints of catalysis

by enzyme-like polymers are covered by T. Kunitake, and those of transition metals by C.V. Pittman Jr. Chapter 6, on synthesis using polymer-supported protecting groups, by J.M.J. Fréchet, includes asymmetric synthesis and preparation of alkaloids, unsymmetrical carotenoids and other interesting syntheses. A sober and thorough assessment of the present scope and limitations of polymer-supported synthesis in general concludes this chapter. The contributions of J.M. Stewart, Fréchet and M.J. Gait describe solid-phase synthesis of peptides, oligosaccharides and oligonucleotides, respectively. Although the peptide and nucleotide topics have been reviewed frequently and in more detail elsewhere, these three skilfully prepared chapters are well worth reading. Solid-

phase oligosaccharide synthesis still needs much work to become competitive. Completing the main text is another chapter by Hodge, on various applications of polymer-supported species. Rounding off the book is an appendix which provides experimental guidance on the art of suspension polymerization, and on chemical modification of polymers.

This useful book gives thorough attention to detail and provides a wealth of clearly drawn illustrations. Research into polymer-supported reactions is a young and growing enterprise. This book should certainly further its development. □

Johannes Meienhofer is in the Chemical Research Department of Hoffmann-La Roche, Inc., Nutley, New Jersey, USA.

Of plants and pathogens

John Friend

Plant Disease: An Advanced Treatise. Vol. 5, How Plants Defend Themselves. Edited by James G. Horsfall and Ellis B. Cowling. Pp.534. ISBN 12-356-4050. (Academic: 1980.) £27.80, \$49.50.

PLANTS have a range of natural defences which enable them to grow successfully and produce healthy crops despite the widespread presence of many potential pathogens. These resistance mechanisms have had an impact on plant evolution and further understanding of the processes is required in order that the mechanisms can be utilized and adapted by plant breeders and agronomists to improve crop production and yield.

In *How Plants Defend Themselves*, the final volume of a multi-author treatise on plant disease, the various ways in which plants resist disease are covered in 23 chapters. The early sections cover well-documented resistance phenomena such as escape from, and tolerance to, disease.

Later contributions deal with preformed barriers to attack, both physical and chemical. Physical barriers may be external, such as specialized types of plant surfaces and their coverings, or internal, including suberized and lignified tissues, gums, resins and silica. Preformed defensive chemicals include relatively simple compounds exuded from roots and specific antifungal and antibacterial compounds, often of chemotaxonomic interest, present inside the plants.

Considerable effort is now being expended on research into active mechanisms of plant resistance to pathogens, a topic which is covered in considerable depth in the book. Recognition and compatibility between host and parasite which are the most important initial events are surveyed in detail by Sequeira, who pays particular

attention to the possible functions of lectins, polysaccharides and lipopolysaccharides. Király reviews hypersensitivity with particular reference to his own recent experiments, and concludes that it is not necessarily the cause of resistance but probably a result of stress that develops in incompatible host-parasite combinations. Following a review of active formation of physical barriers by Beckman, Cruickshank provides a thoughtful review of the phytoalexin concept and the possible roles of phytoalexins in disease resistance.

However, the highlight of the book is a series of five chapters on acquired immunity to a second attempted invasion triggered by an initial infection by viruses, bacteria, fungi, nematodes and insects. In the main these chapters are descriptive, but the two on viruses and bacteria discuss possible mechanisms for this type of resistance which could involve alterations in nucleic acid and protein metabolism.

The phenomena are of great importance for an understanding of resistance mechanisms and may also have practical application in the design of new fungicides.

The book is an excellent summary of the most recent work on plant disease resistance. It can be criticized because it under-emphasizes the stimulus given by plant pathologists to research on the biochemistry and physiology of healthy plants; nevertheless, the reader should realize that the editors deliberately tried to produce a series in which the authors would write reflective articles examining the future of research on plant disease. Despite the rather anthropomorphic chapter headings and the idiosyncratic suggestion that plant resistance is analogous to the defence of a mediaeval castle, this editorial policy has been successful. □

John Friend is Head of the Department of Plant Biology at the University of Hull.

Nature's archives

Robert Olby

Natural History Manuscript Resources in the British Isles. Compiled by G.D.R. Bridson *et al.* Pp.473. ISBN 0-7201-1559-0. (Mansell, London/Bowker, New York: 1980.) £97.

EVER since the establishment and consolidation of local government authorities in the nineteenth century, archive material has been preserved in provincial record offices, public libraries and civic universities on an increasing but uncoordinated basis. Successive parliamentary acts have expanded the list of official repositories for public documents, most of which are held either in a record office under the jurisdiction of the chief executive (formerly the town clerk) or in a public library under the control of the librarian. The scattering of archives between public libraries, record offices, museums, local societies, professional institutions and universities is inevitable given the varied sources generating them and the diversity of the parties interested in studying them. That the reform of local government in 1974 failed to clarify the relationship between the record office and public library is hardly surprising. That there should be some rivalry between civic universities and public libraries over the deposit of documents is to be expected. The important problem is that of guiding the inquirer in his search for source material.

There have been a number of initiatives to offer such guidance and to stimulate the formation of collaborative policy for deposition. The Commission on Historical Manuscripts, which celebrated its centenary in 1969, has played an invaluable role through the National Register of Archives which was established in 1949. Of particular importance for the history of science is the work of the Contemporary Scientific Archives Centre at Oxford.

The initiative for the present work goes back to the 1960s when D.E. Allen, R.H. Ellis and others formulated an ambitious plan to conduct a major search of the country's archives which relate to natural history. In the event adequate funds were not forthcoming and a more modest survey was undertaken by Bridson, Phillips and Harvey. They are to be congratulated for the extent and the detail of their book. There have always been close links between botany, zoology and natural history. Since the beginning of this century experimental biology has distanced itself from the work of the naturalists, but for most of the period covered by this survey students should find this book an aid to research. The only regret is that the authors were unable to include the extensive collections of the Public Record Office at Kew. □

Robert Olby is Reader in the History of Science, Department of Philosophy, University of Leeds.
